No such thorough or representative population screening of paediatric populations has been performed recently in Europe or the USA. Audiometric screening studies of small populations suggests a point prevalence of less than 1 percent in these countries. By contrast, the UK National Study of Hearing found a somewhat higher rate (4.1 percent) of tympanic membrane perforation in the British adult population.¹⁹

Risk factors

A firm understanding of the causes of the exceptionally high prevalence of chronic suppurative otitis media in Inuit and Australian Aboriginals remains elusive. In the past focus has been directed at the biological antecedents of disease. For instance, the racial variations in Eustachian tube anatomy at one time attracted attention as a possible cause for the early onset and persistence of otitis media. Subsequently, nasopharyngeal colonization by a wide variety of otological pathogens became recognized as a more pivotal risk factor.²⁰ Early nasopharyngeal colonization is associated with early acute otitis media,²¹ which in turn is associated with the early onset of tympanic

membrane perforation. More recently, the social factors underlying the biological parameters have been determined. It has been established that these populations acquire pathogens early because of high rates of cross-infection from infected siblings in overcrowded conditions.^{22, 23} This problem also helps to perpetuate the carriage of pathogens, a process assisted by factors that reduce the child's ability to clear the disease (see Table 74.2).

AGE

Data from aboriginal populations indicate a high prevalence of tympanic membrane perforation in very young children with a somewhat lower prevalence in adulthood. The highest rate of perforation is seen in the two- to four-year-old age group, at which stage the rate of perforation is roughly three times the rate seen in adulthood (see Figure 74.3).^{24, 29} By contrast, in South Korea, a rising prevalence with age is found (see Figure 74.4).¹⁸ No information was presented regarding whether these perforations were symptomatic or not, so these data may reflect a steady reduction in perforation rates in childhood over the last 50 years.

TYMPANOSTOMY TUBES

Tympanostomy tube insertion is a recognized cause of subsequent tympanic membrane perforation. A recent review of 62 studies revealed that chronic perforation of the tympanic membrane occurred in 964 of 20,222 ears (4.8 percent).³⁰ Short-term tubes caused chronic perforations in 175 of 8107 ears (2.2 percent). Long-term tubes resulted in chronic perforation in 556 of 3356 ears (16.6 percent). More detailed metaanalysis from eight studies providing separate outcomes for both long-term and short-term tubes indicated that long-term tubes increased the relative risk of chronic perforation by 3.5 (CI: 1.5–7.1)³⁰ compared with short-term tubes.

Table 74.2 Risk factors proposed for high rates of chronic suppurative otitis media in indigenous children.

Risk factor
Early nasopharyngeal acquisition of otological pathogens due to high rates of cross-infection ^{20, 22, 23}
More siblings under the age of five ²⁴
More crowded accommodation ²³
Higher number of siblings with a history of ear inflammation ²³
Prolonged carriage rates of nasopharyngeal pathogens ^{21, 25}
Age at first episode of acute otitis media ²⁶
Poorer nutritional status ²⁷
Reduced exposure to medical services and supportive therapies
Other biological factors
Eustachian tube anatomy
Differences in immune genes ²⁸

Figure 74.3 Point prevalence of ear infection in Australian Aboriginals.²⁹

Figure 74.4 Prevalence rate of tympanic membrane perforation by age in Korea (1991 survey estimates).¹⁸

CLINICAL SYNDROMES

Syndromes that involve skull base, midfacial and Eustachian tube disorders are well known to be associated with an increased prevalence and persistence of otitis media with effusion. The commonest of these disorders are Down syndrome and cleft palate. There is little evidence concerning the prevalence of tympanic membrane disorders in these groups in the literature. One prospective survey of 50 patients has confirmed that those with cleft palate also have a significantly raised prevalence of tympanic membrane perforation (11 percent).³¹ A survey of 201 adults with Down syndrome did not find an increased rate of of tympanic membrane perforation (1 percent).³² This study relied on history, however, and did not include tympanic membrane inspection.

Microbiology

Animal studies reveal that a histological picture of chronic inflammation can be found as early as two weeks after inoculation.³³

A review of studies of microorganisms implicated in chronic suppurative otitis media of at least two weeks duration found that in children, as in adults, the most commonly isolated organism is *Pseudomonas aeruginosa*.³⁴ *P. aeruginosa* is an extracellular opportunistic pathogen that is frequently encountered in chronic infections. It utilizes two major mechanisms to evade

the host defence system. One of these mechanisms is the production of a large number of extracellular products, such as proteases, toxins and lipases. Inhibition of the local immune response by bacterial proteases provides an environment for the colonization and establishment of chronic infection. The other mechanism by which *P. aeruginosa* evades the host defence system is through the production of a biofilm. The biofilm induces a low phagocyte response, and provides a barrier for the bacteria against antibodies, complement and the cells of the immune system.³⁵ Mixed infection is common and other aerobes commonly isolated include *Staphylococcus aureus*, diphtheroids, streptococci and Gram-negative bacilli including *Proteus mirabilis*. Anaerobes and fungi are also reported, although less frequently evaluated. When assessed, *Bacteroides* and *Fusobacterium* species, as well as *Peptococci* and *Peptostreptococci* are found to be common.³⁴ Synergism between anaerobes and aerobes is a widely recognized mechanism for increased virulence in mixed infections and it is notable that intracranial complications of otogenic infection usually have mixed flora including anaerobes.

Clinical presentation

Children with tympanic membrane perforations that are not inflamed may have minimal or no symptoms. Children with tympanic membrane perforations usually have minimal hearing loss except when their ears are discharging or when there is associated ossicular disease. Ear discharge in the presence of a tympanic membrane perforation is usually profuse. The discharge is usually pale and opaque, but not offensive. If the child has received no information on aural health care, the ears may discharge continuously. If the patient knows to keep the ears dry, the ears usually discharge only when water is accidentally admitted into the ear canals or during an upper respiratory tract infection. If the chronic otitis media is associated with profuse granulation or polyp formation, the ear discharge may become bloodstained. Otalgia is unusual in the presence of a tympanic

membrane perforation. Itching is unusual and occurs only when a secondary otitis externa complicates the presentation. Tinnitus and dizziness are very unusual. When they are reported in the presence of tympanic membrane perforation that is actively discharging, examination and investigation to exclude labyrinthine involvement is urgent and essential.

Clinical examination

A child presenting with profuse chronic ear discharge and hearing loss has chronic otitis media in almost all cases. The precise complication of chronic otitis media associated with the symptoms is determined by examination of the tympanic membrane (see **Figure 74.5**), which can only be performed once adequate access to the tympanic membrane has been obtained.

Initial inspection of the ear may reveal mucopus filling the lumen of the ear canal. This can be removed either by suction with microscopic control or by mopping the ear. Most children are frightened by the loud sound caused by aural suction. By contrast, even tiny infants will tolerate mopping very well (see **Figure 74.6**).

Once the ear canal has been cleared, the tympanic membrane should be inspected carefully and systematically. It is a minimum requirement that the entire tympanic membrane be inspected. It should first be determined whether the entire tympanic membrane can be seen. Some ear canals are narrow or tortuous and only part of the tympanic membrane can be seen. **If the attic area cannot be seen then a further examination with the otoendoscope may improve the view.** If this is not

possible in the outpatient department, the child's ear should be inspected **under general anaesthesia**. If the pars flaccida is normal, the pars tensa should be fully inspected.

The general condition of the tympanic membrane should be noted. **A healthy tympanic membrane is only a few cells thick and is translucent.** The incus and features on the medial wall of the mesotympanum are just discernible. The chronically inflamed tympanic membrane is thicker and opaque. The appearance of the tympanic membrane is more homogenous. The blood vessels on the tympanic membrane surface may be more prominent, standing out in contrast to the rest of the drum.

Defects in the pars tensa should be noted, along with their location and size. Whether the defect is a perforation or a retraction pocket should be noted. This cannot always be reliably determined using a hand-held otoscope so inspection using the otological microscope is essential. If this is not possible in the outpatient department, the child's ear should be inspected under general anaesthesia.

Tympanic membrane inflammation associated with the defect should be recorded.

Other tympanic membrane pathology, such as tympanosclerosis or myringitis, should also be documented. An endoscopic photographic image provides a useful alternative view of the tympanic membrane and improves the identification of these extra pathological details.

Features visible through the perforation should be recorded. These include the degree of inflammation of the middle ear mucosa and the integrity of the ossicular chain. Anatomical features on the medial wall of the middle ear space may be visible, particularly if the mucosa is not inflamed.

● Holder Arnold / Scott-Brown 7E

Figure 74.5 Chronic suppurative otitis media. **(a)** In a child with chronic ear discharge, very little information will be gained by inspection of the ear if the physician is unable to clear the ear canal. The child with chronic ear discharge should be considered to have a cholesteatoma until otherwise proven. **(b)** After cleaning the child's ear by mopping with cotton wool until the entire tympanic membrane is visible, the ear discharge in this case is confirmed to be associated with a tympanic membrane perforation with no evidence of cholesteatoma.

© Hodder Arnold / Scott-Brown 7E

Figure 74.6 Aural toilet in small children. Mopping the ear canal with cotton wool is well tolerated in small children. Nonetheless, it is important to keep the head still during the procedure. The child's parent can assist by gently securing the head and limbs as shown. The child can also be visually distracted with an attractive toy.

Investigation

EAR SWAB

A prospective study to evaluate the value of performing microbiological culture of all discharging ears did not show any statistically discernible benefit over empirically treated ears.³⁶

EXAMINATION UNDER ANAESTHETIC

This is rarely necessary as the tympanic membrane perforation can usually be readily identified in the outpatient department after aural mopping. If the child will not tolerate inspection or mopping in the clinic, examination under anaesthetic is necessary to exclude tympanic membrane retraction disease or cholesteatoma.

AUDIOLOGY

Children from the age of four can usually cooperate so that an accurate pure tone audiogram can be obtained. The audiogram will estimate the cochlear and middle ear hearing loss in each ear. Tympanic membrane perforations rarely cause more than 15 dB hearing loss. Larger conductive losses are caused by associated ossicular

pathology. The audiogram may alert the surgeon to this additional problem. Occasionally, associated tympanic membrane pathology, namely tympanic membrane sclerosis, can fix the malleus and cause a greater conductive loss. Significant ipsilateral sensorineural hearing loss may ensure that the patient will not gain any discernible hearing benefit from surgery. Significant contralateral hearing loss may render the patient and surgeon wary of undertaking ear surgery on the ipsilateral ear.

Treatment of ear discharge in the presence of a tympanic membrane perforation

COMMUNITY INTERVENTION

Early uncontrolled reports from Maori and Inuit communities demonstrated a reduction of the prevalence of chronic suppurative otitis media since the introduction of improved housing and better access to healthcare.^{37, 38} These reports have not been replicated in other communities in the past 15 years. The ideal treatment of otorrhoea through a chronic tympanic membrane perforation in high-risk communities should include improvements in nutritional status, in living environment and education about the disease, as well as more overtly medical strategies.³⁹ Despite the identification of risk factors and the introduction of guidelines for the community management of otitis media in severely affected autochthonous populations, there has been no change in prevalence of the disease in the most affected Australian Aboriginal and Inuit communities over the past 20 years.^{40, 41}

There exists only one published controlled community intervention trial of the effectiveness of improving public health or primary care services to a community with a high prevalence of paediatric tympanic membrane perforation. This intervention study assessed the impact of introducing well-managed salt water swimming pools to remote Aboriginal communities where children were swimming in stagnant water holes. A significant reduction in tympanic membrane perforation rates ensued.⁴² [***]

MEDICAL TREATMENT

Most clinicians regard keeping the ears scrupulously dry as the fundamental step in the prevention of chronic ear discharge in the presence of a perforated tympanic membrane. There is no high quality evidence to support this treatment. It may be that belief in the pathological model presented under Repeated infection from the external ear canal is so firmly held that no one has sought to test the treatment based upon it. Possibly, the futility of any treatment plan which does not include this component may be so obvious to clinicians treating

chronic suppurative otitis media that failure to advise patients to keep their ears dry may be considered unethical, and a trial impossible to sanction.⁴³

Nonetheless, the salt-water swimming pool trial in Western Australia (see under Community intervention) raises some questions about this conviction. Whilst the trial principally confirms that swimming in dirty water is worse than swimming in clean water, it does also demonstrate that it is possible for some children to allow water into their perforated ears without the development of chronic ear discharge.

Medical treatment includes aural toilet and the provision of topical or systemic antibiotics, topical steroids and topical antiseptics. A systematic review of these interventions was published in 1998⁴⁴ and has since been updated.⁴⁵ [****] Twenty-four randomized trials were identified. Ten of these trials contained no children and only four trials dealt mainly or exclusively with children.^{46, 47, 48, 49} It should be noted in advance that most randomized trials on this topic are of low quality with few offering near complete follow-up records. Details confirming blinding of investigators, randomization and concealment of treatment allocation, as well as data concerning inclusion and exclusion criteria, measures of compliance as well as recording of drop-outs is often lacking. The metaanalysis of randomized trials of nonsurgical treatment of ear discharge in the presence of a perforated tympanic membrane revealed the following in children.⁴⁴ Aural toilet alone by mopping with cotton wool wisps was no better in alleviating ear discharge than no treatment at all. Two trials were of markedly different design and came to significantly different conclusions on this point.^{46, 47} Topical antibiotics and antiseptics after aural toilet were more effective than no treatment and also more effective than aural toilet alone.^{46, 47} There was no difference in effectiveness between topical antiseptics and topical antibiotics in one study involving children.⁴⁶

In adults (but not specifically studied in children), five studies have found that topical antibiotics and antiseptics were generally more effective than systemic antibiotics. The addition of a systemic antibiotic to a topical antibiotic did not improve the effectiveness of treatment.⁴⁶ Topical quinolones were significantly more effective than other topical or systemic antibiotics in resolving otorrhoea.⁴⁴

None of the papers assessing fluoroquinolones studied in the systematic review included children. More recently, however, a randomized controlled trial in children only has demonstrated a significantly higher cessation of ear discharge with topical ciprofloxacin than a combined antibiotics, steroid and antiseptic preparation.⁴⁹ [****] Eleven studies monitored ototoxicity and these found negligible or no changes in hearing levels after topical treatment.⁴⁴ The treatments were not effective in promoting the healing of the tympanic membrane perforations.⁴⁴

The following recommendations summarize the findings:

- topical antibiotics with aural toilet is the most effective method of treatment; [****]
- quinolones appear to be more effective than other types of antibiotics in resolving otorrhoea; [****]
- antiseptics may be just as effective as antibiotics. [**]

These conclusions are based on short-term outcome measures and, at best, offer guidance to the temporary management of chronic suppurative otitis media.

Aminoglycosides and ototoxicity

Although clinical studies have not identified hearing impairment as an adverse outcome in the medical treatment of ear discharge associated with chronic tympanic membrane perforation,⁴⁵ a review paper in 1993 identified animal studies which associated the use of topical aminoglycosides with ototoxicity.⁵⁰ In accordance with this, the Committee on Safety in Medicines published a guideline in 1997 updating doctors of their 1981 warning that topical aminoglycosides were not indicated in patients with perforated ears. A further committee meeting in 1998 did not consider that a submission from the British Association of Otolaryngologists/Head and Neck Surgeons provided any grounds to reverse this warning. At the time of writing, no topical aminoglycoside is officially recognized for use in patients with perforated ears.

The Clinical Audit and Practice Advisory Group, British Association of Otolaryngologists – Head and Neck Surgeons (ENT-UK) have published a consensus statement on the use of aminoglycoside ear drops in the presence of a tympanic membrane perforation.⁵¹ The advisory group recommend that the following be adopted as guidance.

When treating a patient with a discharging ear in whom there is a perforation or patent grommet:

- if a topical aminoglycoside is used, this should only be in the presence of obvious infection;
- topical aminoglycosides should be used for no longer than two weeks;
- the justification for using topical aminoglycosides should be explained to the patient;
- baseline audiometry should be performed, if possible or practical, before treatment with topical aminoglycosides.

Topical otic fluoroquinolones in children

A randomized controlled trial of 0.3 percent ciprofloxacin drops against framycetin, gramicidin and dexamethasone drops for chronic suppurative otitis media in a paediatric Australian Aboriginal population found a significantly higher rate of elimination of ear discharge in the the ciprofloxacin group.⁴⁹ [****] The study was

double-blinded, the method of allocation was stated, inclusion and exclusion criteria were defined. Almost one-quarter of the original 147 study patients was lost to follow-up. The cure rates were: ciprofloxacin 42 of 55 children (74.6 percent) and framycetin 29 of 56 (51.8 percent). The type of treatment was significantly associated with the outcome ($p=0.009$). The absolute rate difference is 24.6 percent (CI: 15.8 percent, 33.4 percent). There were no confounding factors. There were minor adverse reactions only, with no rate difference between the treatment arms.

A randomized controlled trial of topical ofloxacin against co-amoxiclav in an entirely paediatric population with acute otitis media noted that the topical fluoroquinolone was well tolerated by the paediatric patients. Treatment-related adverse event rates were 31 percent for augmentin and 6 percent for ofloxacin ($p<0.001$). Neither treatment significantly altered hearing acuity.⁵²

A study of the systemic availability of fluoroquinolones after topical application found minimal systemic uptake and side effects from this class of medicines remains low.⁵³

In keeping with their efficacy and lack of side effects in otitis media, the Food and Drug Administration in the USA approved the use of a combined ciprofloxacin and hydrocortisone preparation in 1998. Despite a call for similar approval in the UK,⁵⁴ the Committee of Safety in Medicines has still not recognized this preparation.

Antiseptics

The Cochrane Review⁴⁴ concluded that topical antiseptics may be just as effective as antibiotics. The reviewers recommended that the effectiveness of cheap topical antiseptics should be studied further. Since then only one randomized controlled trial investigating the efficacy of a topical antiseptic in chronic suppurative otitis media has been published. This work investigated the efficacy of three concentrations of aluminium acetate solution. No difference in the cure rate of the 13 and 3.25 percent solutions was found, but a 1.3 percent solution was less effective.⁵⁵ [****] Further work in this area would be of considerable interest as topical antiseptics are cheap.

SURGICAL CLOSURE OF THE TYMPANIC MEMBRANE PERFORATION IN CHILDREN

Spontaneous healing of chronic tympanic membrane perforations is uncommon, and medical interventions are not effective in promoting perforation closure. Surgical intervention is the treatment of choice to effect closure of the perforation. The medical literature provides ample evidence that when this is performed in an adept manner, a high rate of closure is possible in adults, in the short to medium term at least. However, there remains controversy concerning the reperforation rate in children.

Age of the patient

The most important and controversial issue regarding the surgical closure of tympanic membrane perforations in

children is that of the age of the patient at the time of the procedure. Although earlier reports indicated an increased failure rate in small children, studies concluding that age makes no difference now outnumber those that find a difference by five to one. However, in most papers a small sample size leading to insufficient power compromises the accuracy of these conclusions. Because of this limitation, a metaanalysis of paediatric tympanoplasty provides the most authoritative analysis of parameters that correlate with closure of the tympanic membrane. One such study, based on a Medline search of the English language literature, has been published.⁵⁶

Nineteen articles provided sufficient age-related data of surgical outcomes for a linear regression of success rate against age to be performed. Success was defined as an intact tympanic membrane following surgery. The success rate was defined as the number of intact tympanic membranes following surgery divided by the total number undergoing surgery. These data are shown in Figure 74.7.

A more thorough statistical analysis was performed. The mean weighted differences of success rate were calculated by age for each age from 6 to 13 years in one-year increments. Linear regression of this statistic against age in years indicated a significant association of greater success with advancing age ($p<0.005$).

Exclusion of the youngest patients does not eliminate the relationship between success rate and age, for when the analysis is repeated in the age group 9 to 13 years an association persists ($p<0.03$).

Other potential risk factors

In the belief that something that is more prevalent in the younger age groups must account for this result, the same authors sought to identify the cause of this relationship. A metaanalysis of supposed risk factors for surgical failure of tympanic membrane repair was performed using data from 30 studies. None of the following had any discernible influence on the outcome of surgery in comparative studies: perforation size (less versus greater than 50 percent), prior or concurrent adenoidectomy

Figure 74.7 Results of tympanoplasty from 19 published articles according to patient age. Unweighted data (previously unpublished) and regression line are shown. Courtesy of Jeffrey T Vrabec.

(yes/no), status of the contralateral ear (normal/not normal) or Eustachian tube test result (good/poor) (see Table 74.3). They also compared variables between studies which had not been quantitatively assessed within any existing paper: infection at the time of surgery (yes/no) and surgical technique (overlay/underlay) and, again, found no significantly discernible influence on outcome.

Subsequent papers

Since the tympanoplasty metaanalysis, there have been a number of papers describing tympanoplasty with cartilage repair of the tympanic membrane.⁵⁷ The authors suggest that there is no increased rate of tympanic membrane repair failure in small children with this technique. It should be remembered that the same claims were made about fascia repair of the tympanic membrane in small children. Until such time as rigorous analysis of sufficient numbers with age-related data is performed then such claims cannot be regarded as proven.

OTHER AIMS OF SURGICAL CLOSURE OF THE TYMPANIC MEMBRANE

Hearing impairment

It is well established that the hearing impairment caused by tympanic membrane perforations is dependent on the size of the perforation and many tiny perforations cause minimal hearing impairment. In general, the hearing gain from tympanic membrane closure alone is small.

Detailed analysis of hearing outcomes in paediatric tympanoplasty is restricted because of the lack of raw data from existing studies. Pooled data indicate that: 85 percent of 567 children had postoperative speech reception thresholds of less than 30 dB HL; 70 percent had postoperative speech reception thresholds of less than 20 dB HL; 87 percent had a postoperative air-bone gap of less than 20 dB HL.⁵⁶ No correlation of these data with preoperative factors was performed.

Elimination of middle ear pathology

Sheehy and Shelton have suggested that tympanoplasty should eradicate pathological conditions from the middle

ear.⁵⁸ In children, the surgeon may not be able to achieve this aim. Indeed, histological analysis of temporal bones not infrequently identifies the presence of middle ear inflammation behind an intact tympanic membrane.⁴

The following sequelae suggesting the persistence of middle ear inflammation despite closure of the perforation were tabulated in the metaanalysis of paediatric tympanoplasty⁵⁶ – otitis media with effusion: 75/708 (10.6 percent); atelectasis: 31/478 (6.7 percent).

Cases of postoperative cholesteatoma were also seen. These may be iatrogenic or due to progression of disease.

LONG-TERM RESULTS

Long-term follow-up of patients inevitably results in some loss of data as patients move away, are unable to attend or even die from other causes. There are statistical techniques to compensate for this loss of information. Long-term follow-up data which do not use such probabilistic techniques are often meaningless and possibly misleading. The only paper using life-table analysis to study tympanoplasty in children has shown a deterioration over time of the repaired tympanic membrane due to increasing perforation and myringitis. Even at one year following surgery, untreated middle ear inflammation has caused, through effusion, perforation and myringitis, the disease free rate to drop to 0.63 (CI 0.42, 0.81).⁵⁹

TIMING OF TYMPANOPLASTY IN CHILDREN

While the factors causing an increased failure rate in young children have not been unequivocally identified, there appears to be some merit in delaying the operation until such time that the likelihood of surgical failure is minimized (has fallen to or near adult levels). The decision to offer surgical treatment in a child with a tympanic membrane perforation should therefore not be a reflex initiated by sighting the perforation.

A planned delay in surgical treatment prolongs the period during which infection may enter from the ear canal so diligent use of prophylactic manoeuvres must be employed to maintain a dry ear.

Table 74.3 Factors that do not influence the outcome of tympanoplasty in children.

Parameter	Perforation size (less versus greater than 50%)	Prior or concurrent adenoidectomy (Y/N)	Status of the contralateral ear (normal/not)	Eustachian tube test result (good/poor)	Infection at the time of surgery (Y/N)	Surgical technique (underlay/overlay)
Number	388/484 versus 102/147	115/146 versus 187/235	401/495 versus 182/254	83/95 versus 41/ 53	44/60 versus 408/514	872/1069 versus 692/830
WMD	1.46 (CI -25.2, 28.1)	3.10 (CI -23.6, 29.8)	6.48 (CI -15.0, 27.9)	14.69 (CI -20.8, 50.1)	73.31 versus 81.18	88.16 versus 90.40
P	0.91	0.82	0.55	0.42	0.26	0.86

Preventing the ingress of water is the most important of these in the industrial world. For the patient with no interest in swimming the extra care required to control infections may be very small. The child should be taught how to keep water away from the ear when washing. When washing the hair or face, a water-resistant barrier should also be used to exclude any stray drops.

Maintaining a dry ear requires extra care when the child takes an interest in swimming. The options for care include banning swimming or permitting limited surface swimming with the use of a barrier in the ear canal. Since most children greatly enjoy swimming, provision of swim plugs and advice about avoiding diving below the surface of the water should be routinely provided while awaiting surgical closure of the perforation.

It will rarely be possible for the surgeon to confidently offer a discernible improvement in hearing. The most tangible benefit will arise if there exists some compromise of the patient's health or activity by the risk of infection. Some patients with no ear discharge, minimal hearing loss and no compromise of daily activity may justifiably prefer to decline an offer of surgical intervention.

SURGICAL TECHNIQUE

The tympanic membrane perforation may be only one of several complications of chronic otitis media present in the affected ear. These other complications may also affect the tympanic membrane. Tympanosclerosis, atelectasis and myringitis may all be found accompanying a perforation on the same eardrum. The complications may also affect the remainder of the middle ear. Mucosal hyperplasia due to chronic suppurative otitis media may still be present. Ossicular fixation or defects may be evident. The aim of tympanoplasty is to restore the middle ear including the sound transformer.⁵⁸ In keeping with this approach, adequate repair of a tympanic membrane perforation requires adequate repair of the middle ear not just closure of the defect. Thus, the extent of surgery deemed to be adequate varies according to the severity of the disease. Very mild disease may require no more than attention to the perforation alone. More severe disease may require attention to the middle ear space and tympanic membrane, as well as the perforation.

The tympanic membrane may be entirely healthy apart from the presence of a small perforation. In this circumstance the intervention required to close the hole may be no more than excision of the rim of the perforation with the placement of a small graft to close the defect.⁶⁰ The procedure may be performed as a day case and healing occurs within weeks. There is no requirement to pack the ear postoperatively. There are series reported using this technique that have excellent results.⁶¹ [*] A key point for achievement of these results appears to be careful selection of patients.⁶¹

If there is ancillary tympanic membrane disease, treatment of the tympanic membrane as well as the

perforation may be necessary.⁶² [*] Excision of the rim of the perforation remains important. This procedure also requires secure reinforcement of the entire tympanic membrane around the defect so that the graft obturates the perforation and is in contact with the entire rim of the perforation. Although reabsorbable materials are sometimes inserted into the middle ear to support this tissue, it is possible to support the graft on the annulus and manubrium. Because of extensive coexisting tympanic membrane disease, reinforcement of the entire tympanic membrane with temporalis fascia, tragal perichondrium or cartilage is frequently necessary.⁶³ [*]

Grossly inflamed mucosa has been identified as an independent risk factor for later abnormality of the repaired tympanic membrane.⁶⁴ [**] It has been suggested that under this circumstance repair be performed with cartilage rather than temporalis fascia. It is also possible to reduce thickened mucosa that physically impedes placement of a graft. This is most effectively performed with a KTP laser which acts as a haemostat as it vaporizes the excess tissue.

Injury to the mucosa of the medial surface of the middle ear may cause adhesions to the tympanic membrane graft during healing. Division of pre-existing adhesions may promote this. In addition, factors that narrow the slender middle ear cleft, such as thickened middle ear mucosa or retraction of the umbo increase this risk. Under any of the preceding circumstances, it is prudent to insert a barrier to prevent contact between the medial and lateral surfaces during healing. Thin (0.25 mm) silastic or ophthalmic gelfilm are suitable.

Umbo retraction is particularly common in perforations with extensive loss of the inferior part of the tympanic membrane. If the umbo retraction is particularly marked, it may be necessary to disarticulate the ossicular chain to lateralize the manubrium satisfactorily. The malleus head is excised and a malleus to stapes assembly is performed in addition to the tympanic membrane repair. Amputation of the umbo should not be performed as this greatly diminishes acoustic transmission through the middle ear.

Anterior perforations present a great problem to many surgeons (see below). Good access to these perforations can be obtained with an anterior canalplasty.⁶² All suggestions concerning surgical technique are grade D recommendations.

OUTCOMES OF SURGERY FOR TYMPANIC MEMBRANE PERFORATION

The metaanalysis of the surgical repair of tympanic membrane perforations suggests that perforation closure can be expected in 90 percent of cases. It should be that this figure is gleaned from case series proffered by motivated individuals with a special interest in otology in children. More typical figures for success rate by British surgeons seems to be between 74 percent (small

perforation) and 56 percent (large perforation).^{65, 66} This raises a number of important points.

- The surgical repair of the tympanic membrane is a difficult procedure requiring considerable skill.
- There is considerable variation in outcomes from surgeon to surgeon.
- Patients cannot be informed as part of the consent process if no audit of the operating surgeon's results is performed.
- It is debatable whether any surgeon should continue to offer this treatment if his/her success rate for the procedure is as low as 56 percent.
- An appropriate response to audit is essential.
- Training of tympanic membrane repair should include techniques to improve access.

ATROPHY OF THE PARS TENSA OF THE TYMPANIC MEMBRANE (INCLUDING RETRACTION POCKETS)

Introduction

The study of the treatment of pars tensa atrophy and its sequelae is particularly short of high-quality evidence. Consequently this topic is intensely controversial.

Chronic otitis media and the pathology of atrophy of the pars tensa of the tympanic membrane

Atrophy of the pars tensa of the tympanic membrane occurs through loss of the collagenous fibrous layer.⁶⁷ The cause of this pathology is not fully understood; however, pars tensa atrophy is associated with chronic middle ear inflammatory changes in histological studies in human temporal bones.^{68, 69} Animal model studies have demonstrated that pars tensa atrophy can result from middle ear inflammation.^{70, 71}

There is also evidence that some cases of tympanic membrane atrophy are associated with sniffing. In the presence of an open Eustachian tube, sniffing results in a sharp reduction in Eustachian tube and middle ear pressure. An unwanted consequence of the sharp drop in middle ear pressure is retraction of the tympanic membrane.⁷² The stimulus for this behaviour appears to be the sensation of pressure and range of abnormal sounds perceived by the patient during the period that the Eustachian tube is open. The benefit resulting from sniffing is closure of the tube and cessation of the unpleasant symptoms.⁷³ That this behaviour is learnt has been suggested by studies which have identified that the Eustachian tube need not be a passive bystander but is sometimes actively opened in preparation for the sniff.

Following the loss of this stiff structural element, the thinned area of tympanic membrane can be more easily displaced by the pressure difference across the tympanic membrane. The relative negative middle ear pressure found in association with chronic otitis media results in a visible medial displacement ('retraction') of the weakened area.⁶⁹ Reduced middle ear pressures are usually attributed to increased rates of gas exchange across the middle ear mucosa during periods of inflammation, but may be consequent upon gas extraction caused by sniffing.

Should the middle ear pressure be raised, as after sleep, the tympanic membrane may bulge laterally.^{74, 75}

Pars tensa atrophy with retraction may focally affect any segment of the tympanic membrane and may affect the entire tympanic membrane.⁷⁶

The tendency of retraction pockets caused by chronic otitis media to form in the posterosuperior part of the tympanic membrane may be due to a combination of the following factors. The posterosuperior pars tensa is more vascular than other areas of the tympanic membrane and may be subject to more marked inflammatory reactions.⁷⁷ The fibrous layer in this region is less complete and can be devoid of circular fibres.⁷⁸

Atrophy of the pars tensa ranges from mild through to more severe retraction with fixation of the atrophic segment to the bony walls of the middle ear (see **Figure 74.8**). Some cases of tympanic membrane collapse are

© Hodder Arnold / Scott-Brown 7E

Figure 74.8 Retraction of the pars tensa. The tympanic membrane of this seven-year-old girl's ear is atrophic and retracted. The fundus of the retraction pocket is not wholly visible and there is some accumulation of skin in the retracted area. Although there is a fluid level visible behind the anterior part of the tympanic membrane, the ossicular chain is intact and the child's hearing remained normal. Two years after this photograph was taken the girl's ear remains unchanged.

progressive. They may become associated with erosion of the ossicles (see **Figure 74.9**).⁷⁹ A small proportion of advanced pars tensa retraction pockets progress to become cholesteatoma (see **Figure 74.10**).⁸⁰

Definitions and classification

Thus, pars tensa retraction includes not only a range of appearances, but also a clinically important minority which will insidiously deteriorate. Terminology and classifications were specifically designed to attempt to distinguish the high-risk subgroup, which progresses to cholesteatoma.

Sade’s classifications of retraction of the pars tensa of the tympanic membrane defined two types of retraction and classified each on an ordinal scale.

- 1. Atelectasis, defined as diffuse ‘retraction of the tympanic membrane towards the promontorium’ (see **Table 74.4**).⁶⁹
- 2. Retraction pocket, defined as focal ‘retraction of the pars tensa towards or into the attic’.⁷⁹

The distinction between Sade’s two types of retraction has faded, with the terms defined for retraction towards the promontorium now freely used for all pars tensa retractions.

Figure 74.9 Retraction of the pars tensa with ossicular erosion. The tympanic membrane of this young man is almost entirely atrophic and retracted. The fundus of the retraction pocket is not entirely visible but the pocket remains self-cleaning. The manubrium, the long process of the incus and the stapes superstructure have all been eroded. Although there is air in the protympanum, the atrophic tympanic membrane is draped over the facial nerve and the stapes footplate. The last feature has resulted in elevation of the hearing threshold being restricted to 30dB hearing loss. This is his better hearing ear and the hospital notes indicate his ear has remained unchanged for over a decade.

Further classifications of atelectasis have been defined. These have largely followed the original, using an ordinal scale largely based on anatomical features of the retraction pocket. For the most advanced stage of most of these classifications, the definition reflects the role of retraction pockets in the genesis of cholesteatoma by including a nonanatomical feature such as adherence of the pocket or keratin accumulation within the pocket. A recent, innovative classification has also reflected the tendency of retraction pockets to damage the ossicular chain by including an audiometric parameter.⁸¹ No evidence has been presented to date that any of these provides a more precise prediction of disease progression than the Sade classification.

Figure 74.10 Retraction of the pars tensa with cholesteatoma. A small proportion of retraction pockets progress to form cholesteatoma. In this ear there is erosion of the manubrium, the incus, the scutum and the posterior annulus as well as the development of a cholesteatoma. Note that the anterior mesotympanum/protympanum remains ventilated.

Table 74.4 Sade classification of atelectasis.

Grade	Title	Description
1	Retracted ear	Slight retraction of the tympanic membrane
2	Severe retraction	Retraction of the tympanic membrane, touching the incus or the stapes
3 ^a	Atelectasis	Tympanic membrane touching the promontorium
4	Adhesive otitis	Tympanic membrane adherent to the promontorium

^aOf these, stage III was, itself, called ‘tympanic membrane touching the promontorium’ or ‘atelectasis’. The ambiguous nature of the term ‘atelectasis’ has been compounded as the distinction between retraction ‘towards the promontorium’ and ‘towards the attic’ has been neglected. For many surgeons, ‘atelectasis’ has metamorphosed into a term describing any retraction pocket of the pars tensa. Reprinted from Ref. 79, with permission.

Epidemiology of retraction of the tympanic membrane

POPULATION-BASED STUDIES

A population-based survey of 15,890 Navajo children determined the point prevalence of tympanic membrane retraction in this population at 1.9 percent.⁸² Another such survey of 794 children followed up in the Dunedin area of New Zealand identified a point prevalence of 1.3 percent retracted tympanic membranes in this cohort at the age of 15.⁸³

PREVALENCE IN THE POPULATION OF CHILDREN WITH PERSISTENT OTITIS MEDIA WITH EFFUSION

Prospective follow-up of children with persistent otitis media with effusion has confirmed an increase in the prevalence of pars tensa retraction with increasing duration of follow-up. Fifteen percent developed some degree of retraction.^{84, 85} Only 2 percent of patients were found to have advanced (Sade grade III/IV) pars tensa retraction. The age distribution of patients whose retracted tympanic membranes cause sufficient concern to prompt surgery is not necessarily the same as the prevalence of retracted tympanic membranes in the community. The former distribution is shown in (Figure 74.11). This strikingly confirms that intervention for tympanic membrane retraction is predominantly a paediatric problem.

Natural history of progression of retraction of the tympanic membrane

Follow-up of patients with tympanic membrane retraction over a mean of three to five years using the Sade classifications has established the following.

- Retraction without atrophy (grade I atelectasis) is usually a transitory condition. It rarely progresses to more advanced stages and frequently reverts to a normal tympanic membrane. This behaviour is discernibly different to more advanced stages of this disease (see Table 74.5).⁸⁶
- Grades II and III of the disease are quite dynamic, having the ability to improve, deteriorate or remain the same. Over three to five years, 16 percent may be expected to deteriorate.⁷⁹
- Grade IV atelectasis, on the other hand, does not spontaneously revert back to earlier stages of the disease. This is significantly different to the behaviour of the other stages of the disease (see Table 74.5).⁷⁹
- Sixteen percent of grade IV retraction towards the promontory will progress to perforation.⁷⁹
- Ten percent of clean pockets retracting towards the attic will progress to the accumulation of keratin debris.⁷⁹
- A large number of retraction pockets which progress towards the attic present at a late stage.⁷⁹

Figure 74.11 Histogram of age of patient at time of surgical excision of pars tensa retraction pocket.

Table 74.5 Natural history of pars tensa retraction towards the promontory.

Investigator	Sade grade assessed	Change	Probability of change
Tay (1995) ⁸⁶	I	Improve	0.85
	II, III, IV	Improve	0.29
Sade (1981) ⁷⁹	I, II, III	Improve	0.42
	IV	Improve	0
	I, II, III	Worsen	0.17
	IV	Worsen	0.20

It should be noted that the distinction between Sade’s two types of pars tensa retraction has not been widely followed. As a result, the results of the quantitative analysis of the behaviour of retraction towards the promontory has been freely interchanged with that of retraction towards the attic.

The only factor associated with the progression of pars tensa retraction is progression of disease beyond Sade grade I.⁸⁶ In fact, this evidence might more clearly be interpreted as showing that grade I retractions do not progress. Once atrophy has occurred progression is a possibility.

Although the Sade grade remains the most widely accepted adopted means of monitoring disease progression, the risk of deterioration from one grade to the next is low and the classification provides a low predictive value for disease progression.

Symptoms

Retraction of the pars tensa of the tympanic membrane may be associated with a complex and highly variable set of symptoms and signs. These result not just from the atrophy of the tympanic membrane itself, but also from the underlying chronic otitis media, as well as Eustachian tube phenomena. Furthermore, complications of the retraction such as erosion of the ossicles or infection of keratin accumulating within the retraction pocket also contribute to the melange of symptoms.

Frequently there may be **no symptoms** at all. Variable **hearing loss** due to chronic inflammation with accumulation of a middle ear effusion may occur. Persistent hearing loss may result if the tip of the long process of the incus has been eroded. In general, hearing loss is mild when there is a contact between the retracted tympanic membrane and an intact stapes. Erosion of the stapes superstructure results in a larger and more clinically significant conductive hearing loss. **Episodic or recurrent otalgia or otorrhoea** may occur. These may be due to episodes of acute otitis media or infection of debris within the pocket. Some patients with retraction of the pars tensa experience **pain** on performing Valsalva's manoeuvre. Variable sound perception due to variable Eustachian tube patency also occurs.⁷³ For a similar reason, some patients experience a feeling of fullness or pressure in their ears. They find that sniffing, which reduces the middle ear pressure and locks the Eustachian tube, eases this sensation.⁷²

Signs

Examination of the retracted tympanic membrane requires the following steps:

- provision of an adequate view of the tympanic membrane;
- establishing the diagnosis;
- staging the disease.

OBTAINING AN ADEQUATE VIEW OF THE TYMPANIC MEMBRANE

Please refer to Clinical examination in the section on Chronic perforation of the tympanic membrane above.

ESTABLISHING THE DIAGNOSIS

Careful microscopic examination of the retracted pars tensa is required to determine the fine details necessary to diagnose and stage the disease.

Care is required to differentiate a retraction pocket from a perforated tympanic membrane and the two-dimensional view provided by a hand-held otoscope may not be sufficient. The otological microscope will help determine if the retracted area is perforated, if other tympanic membrane disease is present and whether there is any evidence for acute or chronic middle ear inflammation.

If keratin is accumulating within the retraction pocket, some authorities would consider that the pathology is better considered a **cholesteatoma**. However, a minor accumulation of dry keratin, associated with streaming of the keratin out of the retraction pocket, usually remains asymptomatic and is not always associated with disease progression.

STAGING THE RETRACTION POCKET

It is important to attempt to identify the margins and entire fundus of the retraction pocket. It may disappear behind the posterior annulus, the manubrium or the chorda tympani.

The structures under the floor of the retracted tympanic membrane should be carefully inspected. The promontory and round window and ossicles are readily identifiable when the inferior pars tensa is retracted. If there is retraction of the posterior tympanic membrane, the abnormality is readily recognized because the long process of the incus will be clearly visible.

The state of the incus and stapes should be carefully inspected. The retraction may be in contact with the long process of the incus only or may envelop the incus and stapes like clingfilm. The lenticular process of the incus may be eroded so that the capitulum is partly visible. The long process may be eroded so that it no longer makes contact with the stapes. There may be erosion of the posterior annulus so that the stapedius tendon and pyramid are clearly visible. The stapes superstructure may be absent so that the oval window is visible.

There may be keratin accumulating within the pocket. An early sign of this accumulation is a stream of wax emanating from the pocket around the posterior annulus and along the posterior canal wall. In more advanced cases, keratin may accumulate within the retracted area. This may be a generalized feature of the pocket. Keratin accumulation may be focal and associated with areas where the fundus of the pocket is no longer visible.

There may be granulation tissue associated with the retraction if this accumulating keratin becomes infected. There may be granulation tissue within the pocket itself. It may extend onto the adjoining canal wall, in which case the underlying bony annulus may become devitalized (see **Figures 74.8, 74.9 and 74.10**).

Investigations

PURE TONE AUDIOMETRY

Pars tensa retraction pockets cause morbidity not just through progression to cholesteatoma, but also by eroding the ossicular chain resulting in hearing loss. Although ignored in the Sade classification, quantitative assessment of hearing status is an important parameter in the complex process of deciding whether to offer intervention for a retraction pocket. To this end, some classifications require hearing evaluation as part of retraction pocket staging.⁸¹

EXAMINATION UNDER ANAESTHETIC

If the child cannot tolerate aural cleaning in the clinic and inspection of the entire tympanic membrane cannot be performed, examination of the ear under anaesthetic should be arranged.

Management of retraction of the pars tensa of the tympanic membrane

The management of the variable and uncertain behaviour of retracted tympanic membranes is highly controversial. The data presented above under Natural history of progression of retraction of the tympanic membrane indicate that most cases do not progress. Nonetheless, some retracted tympanic membranes progress to form cholesteatoma. At present we cannot predict with certainty which cases will progress. As a result, there are two possible management strategies. The simpler is to wait until cholesteatoma has developed, at which stage intervention is clearly justifiable. The more controversial is to intervene before cholesteatoma develops, using the best available risk factors.

The argument for early intervention asserts that a minor procedure can prevent progression of the disease and the development of complications prior to the development of cholesteatoma. One refinement of this strategy argues that fixation of the tympanic membrane to the promontory is an indication for surgical intervention, since grade IV retractions do not spontaneously improve.

A second scheme proposes that grade III retractions which are progressing are the ideal indication for surgical intervention, since fixation of the tympanic membrane is, itself, associated with a higher incidence of postoperative residual cholesteatoma.^{87, 88} [**] Given that a diagnosis of late stage retraction provides a low positive predictive value for the subsequent emergence of cholesteatoma, this strategy will necessarily result in some patients undergoing an intervention which could be considered unnecessary.

The specific risks associated with surgery for tympanic membrane retraction include the following.

- Surgical elevation of the collapsed tympanic membrane from the ossicles carries some risk of cochlear injury.
- Failure of the tympanic membrane to heal after surgery may result in an iatrogenic perforation.
- There is also a risk of spawning an iatrogenic cholesteatoma by leaving epithelium capable of generating keratin in the mesotympanum in those cases with adherence of the tympanic membrane to the walls of the middle ear.
- Even if the tympanic membrane heals, the tympanic membrane may retract again.

Offering surgery which could be considered unnecessary and which carries some risk of morbidity requires some justification. The justification is that allowing the disease to progress to cholesteatoma exposes the patient to the complications of this disease and condemns the affected patient to extensive surgery as the only treatment option. This, in turn, exposes the patient to a high risk of associated morbidity.

It follows that the debate about intervention pivots on the balance of the risks of surgical intervention at various stages of this progression, as well as the risks associated with the complications of the natural course of the disease. At present, there are no controlled trials of interventions for retraction of the pars tensa. The comparative data required to quantify the above arguments are, therefore, unavailable. Even if such data were already published, the information is unlikely to be generalizable, given the highly operator-dependent nature of the outcome of otological surgery. Since many surgeons performing otological surgery do not keep detailed data about the morbidity associated with their surgery, there is little consensus on the indications for surgical intervention for pars tensa retraction pockets.

Surgical intervention for retraction pockets

GROMMET INSERTION

Treatment of tympanic membrane atelectasis with insertion of a ventilation tube into the remaining healthy tympanic membrane is widely practised. However the best available evidence at present suggests that this treatment does not influence the development of tympanic membrane retraction.^{84, 89} Insertion of multiple ventilation tubes results in more tympanic membrane scarring and no benefit in limiting the progression of tympanic membrane retraction.³⁰

REINFORCEMENT TYMPANOPLASTY

Excision of the retraction pocket with grafting of the tympanic membrane is also widely performed. The graft

material is usually temporalis fascia, perichondrium or cartilage. If the pocket is removed intact there need be no concern about residual disease. If the pocket is adherent to the middle ear walls and tears during removal a second-look procedure may be necessary since the risk of residual disease is as high as with cholesteatoma surgery.⁸⁷ If the retraction pocket is firmly adherent to the ossicles, particularly the stapes, there is a risk of sensorineural hearing loss while removing the disease. Using a KTP laser to remove the disease on the ossicles can lessen this. The laser vaporizes the epithelium and, in contrast to mechanical techniques, does not require movement to remove disease.⁹⁰

RETRACTION POCKET EXCISION

The realization that simple excision of the retraction is usually associated with spontaneous healing of the tympanic membrane has introduced a less invasive procedure for the management of pars tensa retraction pockets (see Figure 74.12).^{91, 92} As this simple operation does not require insertion of a graft, it is simpler than other techniques for tympanic membrane repair, can usually be performed percutaneously, does not require packing of the ear and can be performed as a day case procedure. By virtue of its simplicity, excision of the retraction pocket can be genuinely offered as prophylaxis

against the development of cholesteatoma. The introduction of this procedure has heightened the intensity of the debate concerning the indications for intervention. The results of excision of series of pars tensa retractions are shown in Table 74.6.

Long term results after surgery for retraction pockets

As yet there are no published long-term studies using life table methods of the outcome of surgery on pars tensa retraction pockets. An unpublished, long-term follow-up study of patients in Gloucestershire using life table analysis indicates that many procedures are followed by further retraction of the tympanic membrane (see Figure 74.13). As such, surgery for pars tensa retraction might best be viewed as a temporizing procedure, much in the manner of the insertion of grommets for symptomatic persistent glue ear, rather than a definitive cure.

Table 74.6 Outcomes of tympanic membrane retraction pocket excision.

Figure 74.12 Excision of a tympanic membrane retraction pocket. This child has undergone an Ars-Marquet procedure, in which the tympanic membrane retraction pocket is excised and a minigrommet is inserted through the healthy tympanic membrane remnant. No repair of the defect is undertaken as in the majority of cases the tympanic membrane repairs itself, much as after a traumatic perforation. This 11-year-old girl's tympanic membrane healed normally even though she had an acute otitis media five days after surgery.

Figure 74.13 Life table analysis of long-term follow up after excision of pars tensa retraction pocket. The outcome measure was the development of further atrophy and retraction (at least Sade grade II). The outcome does not indicate the need for reoperation. The data are gleaned predominantly from children operated at Gloucestershire Royal Hospital between 1990 and 1995 (unpublished data).

Ossicular chain defects associated with retraction pockets

The commonest ossicular defect associated with pars tensa tympanic membrane atrophy is erosion of the tip of the long process of the incus.⁹⁷ This can be directly repaired by interposing a graft or prosthesis between the residual long process and the capitulum.^{98, 99, 100} Larger defects of the long process can be repaired by removal of the incus and repositioning it as a malleus-stapes assembly.⁹⁹

CHOLESTEATOMA

Definition

The stratified squamous epithelium of the tympanic membrane and external ear canal can migrate prior to being shed at the entrance to the external meatus. In this way, the ear canal protects itself from filling with shed keratinocytes.

Under some circumstances, squamous epithelium accumulates within the temporal bone. If the squamous epithelium and accumulating keratinocytes are within the middle ear space, this condition is termed 'cholesteatoma'.¹⁰¹

Failure of epithelial migration and accumulation of keratin within the ear canal (or surgically modified ear canal) is not generally termed cholesteatoma. However, if there is also focal erosion of external ear canal bone in association with keratin accumulation some authorities term this 'external canal cholesteatoma'.

Pathogenesis and classification

Following the ascendancy of histological examination for pathological diagnosis in the mid-nineteenth century, early theories that cholesteatoma was a tumour were superseded by hypotheses that the condition was due either to a vestigial structure or a metaplastic process. This distinction between congenital and acquired forms of cholesteatoma remains important to this day, particularly in children.

Congenital cholesteatoma

Keratin cysts may accumulate because the epithelium from which they arise is closed. In general, such cysts may arise as a result of developmental abnormality or may be iatrogenic. Epidermal cysts which are found medial to an intact tympanic membrane (see **Figure 74.14**) are considered to be 'congenital' if they fulfil the criteria of Derlaki and Clemis:

- white mass medial to an intact tympanic membrane;
- normal pars tensa and flaccida;

© Hoesler Arnold / Scott-Brown 7E

Figure 74.14 Congenital cholesteatoma. This three-year-old boy presented with hearing loss and in addition to glue ear was noted to have a white mass behind the anterosuperior part of the intact tympanic membrane. He had no previous history of surgical intervention and satisfied the criteria for congenital cholesteatoma. The epidermoid cyst was removed intact and the ossicular chain was preserved. His hearing remains normal.

- no previous history of ear discharge, perforation or previous otological procedures;¹⁰²
- it has been proposed that prior bouts of acute otitis media are not grounds for excluding the possibility of congenital cholesteatoma since it is very rare for a child to have no episodes of otitis media in its first five years.¹⁰³

A vestigial structure, the epidermoid formation, from which congenital cholesteatoma may originate has been identified in the anterior epitympanum.¹⁰⁴ However, not all congenital cholesteatomas are located anterosuperiorly¹⁰⁵ and not all are found to be epithelial cysts.¹⁰⁶ It therefore remains possible that other processes, such as the invagination of squamous epithelium from the developing ear canal¹⁰⁷ or the ingestion of squamous elements in amniotic fluid,¹⁰⁸ may be involved.

Some epithelial cysts that satisfy the definition of a congenital cholesteatoma do not present until the fourth or fifth decade. It has been suggested that the origins of these may in fact be metaplastic¹⁰⁹ or acquired from the aberrant resolution of a pars tensa retraction pocket.¹¹⁰

Surgical causes of middle ear epithelial cysts include failure to completely remove a previous cholesteatoma or implantation of squamous epithelium as a consequence of careless handling of normal tympanic membrane.

Acquired cholesteatoma

More commonly, keratin accumulates within a diverticulum of tympanic membrane squamous epithelium which

extends into the middle ear. Even though this structure communicates with the external ear, keratin accumulates as a result of inadequate epithelial migration.

Recognized mechanisms leading to such acquired cholesteatoma include the following.

- **Immigration:** migration of squamous epithelium into the middle ear through a defect in the tympanic membrane.¹¹¹ While this mechanism continues to be recognized, it is responsible for only a very small proportion of cholesteatomas.
- **Retraction:** progressive retraction of the tympanic membrane, either in the pars flaccida or associated with atrophy of the pars tensa.¹¹²
- **Basal cell hyperplasia:** proliferation of the basal layers of the keratinizing epithelium of pars flaccida.¹¹³

Animal models have confirmed that squamous epithelial proliferation is promoted by chronic middle ear inflammation.¹¹³

The distinction between congenital and acquired cholesteatoma may be blurred by the following mechanisms.

- **Metaplasia:** epithelial transformation from the columnar endothelium of the middle ear cleft into keratinizing epithelium in response to chronic middle ear inflammation.¹⁰⁹ This acquired cholesteatoma gives rise to epithelial cysts.
- Some apparently acquired cholesteatoma may be due to late perforation of congenital epithelial cysts through the tympanic membrane.
- A mechanism whereby a retraction cholesteatoma might present behind an intact tympanic membrane has recently been proposed.¹¹⁰

Iatrogenic cholesteatoma

Implantation of squamous epithelium as a result of blunt or sharp trauma to the tympanic membrane may result in a cholesteatoma. The otologist must always be aware of this possibility when operating on the tympanic membrane. Failure to remove all squamous epithelium from the middle ear during cholesteatoma allows the disease to persist and return. This iatrogenic form is known as ‘residual’ cholesteatoma. Cholesteatoma that returns *de novo* after surgery is termed ‘recurrent’ (see Table 74.7).

Epidemiology

INCIDENCE

Estimates based on retrospective analysis of hospital operation data and the population served have demonstrated an incidence of 0.3/10,000 per year in Denmark,¹¹⁴ 0.7/10,000 per year in children in Iowa,¹¹⁵ 0.9/10,000 per

Table 74.7 Classification of cholesteatoma by aetiology.

Congenital	Acquired
Vestigial	Invagination
Hamartoma	Invasion
Metaplasia	Basal cell hyperplasia
Invagination	Metaplasia
Amniotic migration	Trauma
	Iatrogenic (residual)

year in Finland,¹¹⁶ 1.3/10,000 per year in Scotland¹¹⁷ and 0.1–1.6/10,000 per year in Northern Ireland.¹¹⁸ Extremes of 0.04/10,000 per year in Gothenburg¹¹⁹ and 6.6/10,000 per year in Israel¹²⁰ have also been reported.

PREVALENCE

It is possible to estimate the prevalence of cholesteatoma from epidemiological studies of tympanic membrane disorders. These population-based studies generally observe a population of less than 10,000 patients and may not be accurate if the prevalence of cholesteatoma is very low. A survey in Jerusalem has suggested a prevalence of cholesteatoma as high as 7/10,000 children,¹²¹ with a survey in Vietnam suggesting a similar prevalence of 6/10,000 children.¹²² The Inuit population, which has a high incidence of chronic suppurative otitis media, has a somewhat lower prevalence of cholesteatoma – 0.5/10,000 in a population-based survey of children.¹²³ In Aboriginal children, the prevalence of cholesteatoma was 5/10,000 in a study of 7326 ears.¹²⁴

CHANGE IN PREVALENCE

The change in the incidence of cholesteatoma over recent decades varies from report to report. In Northern Ireland¹¹⁸ and Scotland,¹¹⁷ no change in the incidence of cholesteatoma has been demonstrated. Over the same period in Finland,¹¹⁶ Israel¹²⁰ and Merseyside,¹²⁵ by contrast, a drop in the prevalence of cholesteatoma has been noted.

AGE DISTRIBUTION

The age and sex distribution of the patients undergoing cholesteatoma surgery in a population-based study from Iowa a quarter of a century ago¹¹⁵ is shown in Figure 74.15. The peak incidence in the second decade of life corresponds well with information collected from a database of patients undergoing cholesteatoma surgery in Gloucestershire from 1980 to 2002 (see Figure 74.16).

SEX

Cholesteatoma affects approximately three males for every two females. The proportion of males to females

Figure 74.15 Incidence of cholesteatoma by age in Iowa in 1975/6. Redrawn from Ref. 115, with permission.

Figure 74.16 Cumulative prevalence of cholesteatoma by age in Gloucestershire 1980–2002. Previously unpublished data.

in childhood in the population aged less than 16 years is not statistically different to the ratio in adulthood (see **Table 74.8**).

ANATOMICAL FEATURES OF CHOLESTEATOMA

The distribution of tympanic membrane pathology in cholesteatoma in children is different to that of adults. In children there is a significantly higher rate of cholesteatoma associated with pars tensa pathology than in adults (see **Figure 74.17**). In adults attic cholesteatoma is more frequent (see **Table 74.9**).

EXTENT OF CHOLESTEATOMA

The spread of middle ear cholesteatoma through the temporal bone is also different in children compared with adults. Paediatric cholesteatoma more frequently involves the extremes of the middle ear space (the Eustachian tube, the anterior mesotympanum, the retrolabyrinthine area and the mastoid tip) than cholesteatoma in adults. Adult cholesteatoma, however, more frequently involves the anterior epitympanum (see **Table 74.10**).

Symptoms

Children with cholesteatoma are nearly always affected by either ear discharge or hearing loss, or both, in the

© Hodder Arnold / Scott-Brown 7E

Figure 74.17 Posterior mesotympanic cholesteatoma. Cholesteatoma extending from this part of the tympanic membrane is more frequent in children than in adults. Involvement of the posterior mesotympanum commonly results in erosion of the long process of the incus and less frequently the stapes superstructure. Involvement of posterior mesotympanum and sinus tympani is a recognized risk factor for residual cholesteatoma after surgery. This six-year-old boy had loss of the stapes superstructure and although a malleus to footplate prosthesis was inserted he does not have useful hearing in this ear.

Signs

A child presenting with profuse ear discharge and hearing loss has symptoms caused by chronic otitis media until proven otherwise. The precise complication of chronic otitis media associated with the symptoms is determined by examination of the tympanic membrane. Thus the diagnosis of cholesteatoma is not made and, more importantly, cholesteatoma cannot be excluded until the entire tympanic membrane has been examined. Inspection of the ear often requires two stages: obtaining a view of the tympanic membrane and systematic examination of the tympanic membrane.

OBTAINING A VIEW OF THE TYMPANIC MEMBRANE

Mucus, keratin, polyps or even wax may prevent a clear view of the eardrum. The reader is referred to Clinical examination under Chronic perforation of the tympanic membrane above for the general approach to cleaning children's ears (see **Figure 74.6**). Once the debris has been removed from the child's ear, further inspection may reveal the presence of a polyp filling the lumen. Aural polyps associated with mucopus are almost always due to exuberant granulation tissue. The collagen content of polyps is very low so that most can be avulsed painlessly using microsuction. Once the polyp has been removed its base can be cauterized with silver nitrate to obtain haemostasis.

INSPECTION OF THE TYMPANIC MEMBRANE

Once the tympanic membrane can be clearly seen, it should be systematically inspected for areas of retraction.

It should first be determined whether the entire tympanic membrane can be seen. Some ear canals are narrow or tortuous and only part of the tympanic membrane can be seen. It is a minimum requirement that the entire tympanic membrane be inspected. If this is not possible in the outpatient department the child's ear should be inspected under general anaesthesia.

Defects in the pars tensa should be noted, along with their location and size. Most important of all to note is whether the defect is a perforation or a retraction pocket. This cannot always be reliably determined using a hand-held otoscope, so inspection using the otological microscope is essential. If this is not possible in the outpatient department, the child's ear should be inspected under general anaesthesia.

If the pars tensa is normal, the pars flaccida should be fully inspected. Considerable care may be required to exclude an attic cholesteatoma. In most cases, retraction of the pars flaccida can be readily identified. Some attic retractions, however, can barely be seen even on prolonged and careful examination. They may have a very narrow opening. The anatomy of the ear canal may limit the view of the area. If the attic area cannot be seen then a further examination with the otoendoscope may improve the view. If this is not possible in the outpatient department, the child's ear should be inspected under general anaesthesia. The attic area may be obscured by polyps, keratin or even apparently innocuous mucus or wax. Wax and mucus covering the attic area should be removed. Granulation tissue and moist keratin within this area confirms the diagnosis.

On occasion, a cholesteatoma sac can be seen through an otherwise normal tympanic membrane as a vague white mass with a convex border. A myringotomy to remove any middle ear mucus may help to clarify this sign. Occasionally, a limited tympanotomy may be required to confirm the diagnosis. Rarely such mesotympanic disease may have an attic origin so a further inspection of the attic should be performed.

Investigation of cholesteatoma

AUDIOLOGY

The patient's ipsilateral middle ear hearing function may change as a result of cholesteatoma surgery. It may be unaffected, impaired or improved. The impact this will have on the patient depends on not just the operation but also the preoperative hearing in each of the patient's ears. It is therefore essential to obtain a measure of the hearing in both ears prior to surgery.

With the information provided by a preoperative audiogram, the surgeon can plan for the possible

outcomes of surgery and advise the patient on these possibilities.

- In all cases the patient should be advised that the hearing in the operated ear may deteriorate.
- If the preoperative ipsilateral air conduction is normal, loss of hearing in the operated ear will have more impact if the contralateral hearing is impaired. It is therefore essential that the opposite air conduction threshold be determined so that any appropriate mitigating action, such as the provision of a hearing aid, can be planned.
- If the preoperative ipsilateral air conduction is impaired, the possibility of improving the hearing through surgery should be determined. The ipsilateral bone conduction threshold is essential under these circumstances. If it is also impaired the patient should be advised that improvement in hearing effected by surgery alone is unlikely. If the bone conduction threshold is normal, there remains a chance that the hearing can be improved by surgery, but the likelihood of this happening will depend on the cause of the hearing loss.

EXAMINATION UNDER ANAESTHETIC

This procedure may be essential in small children in order to inspect the tympanic membrane closely. Since acquired cholesteatomas arise from the tympanic membrane, the majority can be diagnosed with this evaluation. Nonetheless, it is important to realize that even acquired cholesteatomas, particularly in the attic, may be difficult to identify and a systematic and careful exploration of the tympanic membrane, including the attic area, is essential. A fine sucker is a useful multipurpose probe, retractor and elevator, as well as microsucker in this venture.

COMPUTED TOMOGRAPHY OF TEMPORAL BONE

In most cases, cholesteatoma is diagnosed by direct inspection of the tympanic membrane. Computed tomography (CT) may be of value in establishing a diagnosis of cholesteatoma under the following circumstances:¹²⁶

- indeterminate examination under anaesthesia;
- suspected epidermal cyst;
- symptomatic ear with apparently clear attic retraction pocket.

CT scan also may be of value in planning the operation when the following particulars pertain:

- revision cholesteatoma surgery;
- suspected inner ear complication;
- suspected intracranial complication.

This information can improve the planning of the case and inform the patient and family of risks specific to the operation.

CT scanning is not valuable in every case. However, the benefit the surgeon gains from the scan parallels his/her ability to interpret it. Accordingly, there exists a body of opinion which feels that expertise in interpreting temporal bone CT scans can only come by regular assessment of scans. Furthermore, scan definition continues to improve, hence all opportunities to view new scans should be taken and therefore all cholesteatoma cases should include CT investigation.

MAGNETIC RESONANCE SCAN OF TEMPORAL BONE

Magnetic resonance (MR) scans are currently of less general use in the assessment of cholesteatoma than CT scans because they lack any information about the bony anatomy of the temporal bone.

Although cholesteatoma has specific signal characteristics (see Table 74.12), MR scan does not yet adequately discriminate between other chronic middle ear inflammation and cholesteatoma, especially when the cholesteatoma is less than 0.5 cm in diameter. This limits the role of MR scan as a diagnostic test and, in particular, means that it cannot be used yet as a screening tool to diagnose residual cholesteatoma after first stage intact canal wall surgery.¹²⁷

Improvements with diffusion scanning and delayed contrast-enhanced multiplanar imaging may encourage the use of MR as a tool for diagnosing residual cholesteatoma.¹²⁸ MR scanning is of particular value in determining the presence of suspected inner ear and intracranial complications of cholesteatoma.

Treatment

MEDICAL

Cholesteatoma is a relentless disease. Once the diagnosis of cholesteatoma has been established in a child who can tolerate a general anaesthetic, there is no justification for withholding the surgical removal of the keratin matrix.

SURGICAL

The definitive treatment of cholesteatoma is surgical.

Table 74.12 MR characteristics of cholesteatoma.

Image character	Signal character
T1 (unenhanced)	Low
T1 (with gadolinium)	Low
T2	High

Aims

The aims of cholesteatoma surgery are:

- removal of all cholesteatoma;
- prevention of the development of further cholesteatoma;
- to obtain a ‘robust’ ear, which remains dry, self-cleaning and free of infection after exposure to water;
- restoration of hearing.

Removal of cholesteatoma encourages radical resection of the mastoid air cells and removal of the posterior and superior ear canal wall to obtain good exposure of the disease. By contrast, maintaining a dry, hearing ear, requires a conservative technique with the preservation or reconstruction of important functional elements. The treatment of cholesteatoma therefore requires the resolution of aims that are antagonistic. This ensures that the successful treatment of cholesteatoma is one of the most challenging endeavours in the entire spectrum of surgical intervention.

REMOVAL OF ALL CHOLESTEATOMA

It is well established that there is a high rate of disease left within the temporal bone (‘residual’ disease) after primary surgery, whatever the surgical technique. This has been emphasized in many retrospective reviews,¹²⁹ as well as in one prospective, controlled trial.¹³⁰

Three retrospective analyses of risk factors for residual cholesteatoma, two specifically in children, using multivariate analysis have been published.^{87, 131, 132} The presence of the factors listed in Table 74.13 independently heightened the risk of residual disease. These results emphasize not only that the temporal bone is a highly complex and heterogeneous anatomical structure but also that the disease is capable of insinuating its way into the interstices of this configuration. The results also confirm that it is particularly difficult to remove disease from the posterior mesotympanum/sinus tympani and from around the ossicular chain.

Improvements in the complete clearance of cholesteatoma have come partly through technological advances that appropriately confront the difficulties presented by the disease and the terrain. Significant advances have been

in visual access to the disease and instruments for removal of the disease from around the ossicles. Thus angled endoscopes or mirrors must be available in order that cholesteatoma lurking in the sinus tympani or behind the ossicles can be clearly seen.

The most significant improvement has come from the introduction of the fibre-guided laser as a tool for removing cholesteatoma from around the ossicles (see Figure 74.18). Adjacent to the ossicles, removal of disease is improved by using an instrument which does not cause movement of the ossicular chain and which can be passed into the recesses of the posterior mesotympanum, as well as those spaces behind the ossicular chain. The fibre-guided laser fulfils the requirements for removal of cholesteatoma in these areas.

A prospective trial of cholesteatoma surgery with and without a KTP laser has confirmed that the rate of residual disease is lower by a whole order of magnitude when the laser is used.¹³² [***] The results are shown in Table 74.14.

Figure 74.18 Removal of firmly adherent cholesteatoma from the intact ossicular chain. Until recently the surgeon could not avulse firmly adherent cholesteatoma from the intact ossicular chain for fear of causing cochlear damage. The most prudent course of action was to dismantle the chain. The fibre-guided laser can vaporize this cholesteatoma without ossicular movement, thereby achieving the conflicting aims of disease removal and hearing preservation.

Table 74.13 Risk factors for residual cholesteatoma in children.^{87, 131, 133}

Risk factor
Erosion of the ossicular chain
Presence of posterior mesotympanic cholesteatoma, especially if adherent
Presence of inflamed middle ear mucosa

OBTAIN A ROBUST, DRY EAR

The presence of an unstable ear after surgery is an ongoing burden to the affected child. The ear may feel uncomfortable and may be associated with otitis externa or excoriation of the pinna. The child may be unable to escape a cycle of regular visits to the ENT department for aural toilet. The discharging ear may exacerbate hearing loss by preventing the use of a hearing aid. A child with an ear that will not tolerate exposure to water may, at the least, need to learn protective measures to prevent the ingress of water to the ear and may be excluded from swimming. Sometimes the ear may continually smell offensive. In this sad circumstance the child may become isolated by his or her peers.

The stability of the external element of the ear is dependent upon the self-cleaning mechanism. This mechanism can continue to act when the ear canal is surgically enlarged, up to a point. There is thus some latitude within which the resolution of the conflicting aims stated above can be achieved. This has allowed the development of a variety of procedures for the removal of cholesteatoma. A dry ear after cholesteatoma surgery can be achieved by:

- working around the intact ear canal wall, gaining access to disease using a combined approach through the mastoid air cells and ear canal;
- lowering the canal wall and incorporating the mastoid space into the canal only in temporal bones with a small mastoid air cell system;
- partially obliterating the mastoid bowl after its exposure by removing the canal wall.

The greatest advantage of intact canal wall surgery is that the resultant ear is almost always dry. [**]

Removal of the canal wall and dissection through the mastoid air cells to facilitate the removal of disease less reliably results in a dry ear. If heed is paid only to the 'disease removal' aim of cholesteatoma surgery, then the ear canal wall may be removed without care, making the mastoid bowl part of the subsequent ear canal. If the surgically created canal is irregular, the self-cleaning mechanism fails and the canal either collects keratin or fails to maintain a keratinizing epithelium or both. Only if this bowl is smooth and free of recesses will the new canal tolerate exposure to the external environment. [*]

Multivariate analysis of factors influencing the stability of the mastoid cavity has indicated that adequate lowering of the facial ridge is the most important factor influencing the outcome of a dry ear in canal wall down surgery.¹³⁴ [**]

PREVENTION OF RECURRENT CHOLESTEATOMA

Cholesteatoma also has a tendency to return *de novo*. This is particularly the case if there exists the combination of a large space behind the plane of the keratinizing epithelium, as well as a small opening through which

the keratinizing epithelium can retract. This will allow the formation of a new narrow-necked sac with subsequent accumulation of keratin ('recurrent' cholesteatoma). Clearly, these circumstances are most likely after intact canal wall surgery although they can also occur after partial obliteration of a large cavity or when a small cavity is attempted in a well-pneumatized temporal bone.

The return of cholesteatoma is partly dependent on the time elapsed since surgery.¹³⁵ It is therefore inadequate to baldly state a simple figure as a percentage of patients in whom cholesteatoma has recurred. At the very least the figure should be qualified by the duration of follow-up.

Provided that temporal information about the thoroughness of follow-up, as well as disease recurrence is available, it is possible to calculate the conditional probability of disease recurring in a particular time interval given that it has not recurred by the beginning of that interval. The technique is called life table analysis and provides useful long-term follow-up data. Two studies using life table analysis have confirmed the higher rate of recurrent disease in canal wall up surgery (see Figure 74.19).^{135, 136} [***]

However, improved surgical technique has corrected this deficiency in the intact canal wall technique. Long-term recurrence rates have been reduced to levels seen in good canal wall down surgery by taking great care to reconstruct any defect through which the disease may return and by staging the surgery. The materials most commonly used for this reconstruction are cartilage and bone pate. One prospective trial of cartilage against bone pate for the repair of such defects has shown no significant difference between the treatment groups in the rate of return of cholesteatoma up to five years after surgery.¹³⁷ [***]

Staging of intact canal wall surgery, originally introduced to permit a check for the presence of residual cholesteatoma, allows an opportunity to inspect the scutum repair. This offers an opportunity to repair any persisting

Figure 74.19 Longstanding concerns exist about the rate of recurrent disease with canal wall up surgery. Comparison of recurrence rates of cholesteatoma after single-stage canal wall up (CWU) and canal wall down (CWD) surgery published in 1989. These data encapsulate the widely perceived disadvantage of canal wall preservation in cholesteatoma surgery. Advances in canal wall reconstruction with bone pate or cartilage have now reduced the recurrence rate (see Figure 74.21).¹³⁵

© Hoelder Arnold / Scott-Brown 7E

Figure 74.20 Prevention of recurrent cholesteatoma when the canal wall is preserved. Preservation of the intact canal wall was formerly associated with high rates of recurrent cholesteatoma. Reconstruction of the lateral attic wall with bone pate stabilized on a rigid support, such as the silastic strut seen in the plate, has resulted in recurrence rates after intact canal wall surgery being reduced to the levels associated with canal wall down surgery. Nonetheless, recurrence in children remains higher than in adults.

Figure 74.21 Actuarial recurrence rates of cholesteatoma in children and adults after staged intact canal wall surgery with bone pate repair of the lateral attic wall. Previously unpublished data.

defect. Rates of residual cholesteatoma after staged bone pate repair of the scutum are comparable to those seen in canal wall down surgery (see **Figure 74.20**).¹³⁸

The rate of cholesteatoma recurrence in children is compared with the rate in adults in **Figure 74.21**. Both groups underwent staged intact canal wall surgery with repair of the lateral attic wall using bone pate. Children have a slightly higher risk of developing recurrent cholesteatoma. [**]

OSSICULAR EROSION IN CHRONIC OTITIS MEDIA

Epidemiology

Chronic otitis media is associated with erosion of the ossicles. Pars tensa retraction pockets and cholesteatoma

are often associated with ossicular erosion.¹³⁹ The commonest defect is erosion of the long process of the incus.⁹⁷ Erosion of any of the ossicles can occur, but erosion of the entire chain is uncommon.

Pathology

Loss of ossicular integrity secondary to chronic otitis media has been termed resorptive osteitis.¹⁴⁰ The cause of this erosion appears to involve inflammatory cells secreting collagenases. Other pathological processes that contribute to hearing loss include tympanosclerosis, fibrocystic sclerosis, sclerosing osteitis and fibrosis of the tympanic membrane, as well as tympanic membrane perforation.¹⁴¹

Classification

Reconstruction of the ossicular chain by interposing rigid prostheses, including the patient's own ossicular remnants, is possible. The geometry of the ossicular defect does not always lend itself to stability of the prosthesis so some reconstructions are more favoured than others. Reconstruction is usually performed between the tympanic membrane, manubrium or long process of incus on the one hand and the capitulum, stapes footplate or vestibule on the other.

There are many surgical techniques for restoring contact between the tympanic membrane and the oval window by bridging the defects in the ossicular chain. Various classifications of this work have arisen.

- Wullstein's original classification of middle ear repair preceded the development of ossicular surgery and is simply based on a topographical sequence of places on the ossicular chain onto which the tympanic membrane could be placed.¹⁴² Although based on procedures which in some cases soon became obsolete, the influence of this classification has been considerable. A number of subsequent classifications of tympanoplasty have adapted the Wullstein system to incorporate ossicular reconstruction.¹⁴³
- Some classifications of ossiculoplasty alone are also based on the nature of the preoperative defect.¹⁴⁴
- Further classifications of ossiculoplasty also incorporate information about the manner of reconstruction.¹⁴⁵

Outcome measures

The success of middle ear reconstruction is often measured by the magnitude of the conductive hearing loss in the operated ear. This measure of middle ear function is of technical value to surgeons comparing surgical techniques, but is not of itself of much relevance to the patient, as the operated ear may also be afflicted by

sensorineural hearing loss. The value of the end result to the patient is more reliably indicated by the overall hearing loss.¹⁴⁶

The contribution of the hearing in the operated ear needs also to be evaluated in the context of the hearing in the opposite ear.¹⁴⁶ These effects are concisely summarized by the 'Belfast rules of thumb',¹⁴⁷ which state that the postoperative hearing in the operated ear will be useful to the patient if:

1. the air conduction threshold is less than 30 db HL (regardless of the hearing in the opposite ear);
2. the air conduction threshold is within 15 db HL of the air conduction threshold in a better contralateral ear.

These effects are also summarized in the 'Glasgow benefit plot'.¹⁴⁸

Risk factors

Three studies have performed multivariate analysis of the factors which influence the audiological outcome of ossicular reconstruction.^{149, 150, 151} The outcome measure in each of these was the difference between the air-bone gap, considered to be a reasonable guide to the magnitude of the conductive hearing loss. In one of these studies,¹⁴⁹ detailed analysis was limited by a small sample size: the only independent risk factor for good audiological outcome was the presence of the stapes superstructure. A larger sample size permitted the assessment of more baseline variates and determined that the presence of the manubrium and stapes superstructure together was the most important predictor of good hearing outcome after surgery.¹⁵¹ By contrast, the absence of the stapes superstructure predicted strongly against a good outcome (see Table 74.15).

This type of study is limited by the quality of the entry data. There are many types of ossiculoplasty and if a type of ossiculoplasty is not included in the entry data, no conclusions can be formulated concerning the relative efficacy of that procedure. For instance, no multivariate assessment of newer procedures, such as malleostapedotomy or malleus dislocation, is available.

Table 74.15 Parameters found to be independently and statistically significant predictors of outcome in ossicular surgery.

	<i>P</i> (multivariate analysis) ¹
Manubrium +, stapes arch +	<0.0001
Stapes only	<0.001
Preop air-bone gap >50 dB (negative indicator)	<0.01

¹Multivariate analysis using a logistic regression model on the outcome of 600 cases of ossicular surgery.¹⁵⁰

Three scoring systems have been formulated which are intended to indicate the outcome of ossicular reconstruction. Only the most recent system is based on multivariate analysis of risk factors. It has not been applied to other surgeons' data.¹⁵² The earlier systems did not provide any useful predictive value when applied to other surgeons' data.¹⁵¹

Results

Two prospective controlled studies of ossicular reconstruction have been performed. Mangham and Lindemann compared two materials in the reconstruction of ossicular defects.¹⁵³ They found no difference between the two materials; however, they did discern a difference between the two surgeons' results. [****] Maassen and Zenner reported a study comparing two different techniques for the reconstruction of the eroded long process of the incus. They found that reconnecting the long process to the stapes head provided significantly better closure of the air-bone gap than malleus to stapes reconstruction.¹⁵⁴ However, no account of the surgeons performing the procedures was provided. [****]

LONG-TERM RESULTS

One actuarial study on long-term hearing, using an outcome similar to the Belfast rules, after surgery for cholesteatoma has been presented (see Figure 74.22).¹⁵⁵ [**] This confirmed the following:

- Hearing outcome was dependent on the state of the ossicular chain prior to surgery. In general, the more intact the chain prior to surgery, the more effective the reconstruction.
- There is nearly always good hearing in the presence of an intact ossicular chain.
- The success of surgery ranged from 40 percent when the stapes superstructure was absent to 89 percent for restoration of an intact chain through reconstruction of the long process of the incus.
- Most differences in success rates for the different types of reconstruction were due to failure before the first evaluation.
- Late failure was uncommon.
- The presence of even mild sensorineural hearing loss limited the usefulness of any ossicular reconstruction. This subgroup contributed heavily to the early failures.
- A higher rate of useful hearing in children is largely due to their better cochlear function (Table 74.16).
- It is worth reflecting on whether any ossicular reconstruction should be performed in an ear with sensorineural hearing loss, particularly if there is little of the remaining chain. Under these circumstances, a hearing aid may offer some benefit provided that the external ear canal is stable.

Figure 74.22 Long-term results of ossiculoplasty. These data show that although there is some deterioration in useful hearing with time, the value of the intervention is mainly determined at the time of surgery. Hearing is measured here as 'useful' if the air conduction threshold in the operated ear is less than 30 dB ISO. This outcome is slightly more stringent than the more widely used Belfast rules of thumb. The data were gleaned from surgery on both children and adults.

Table 74.16 Hearing results (dB HL) after ossiculoplasty (performed as part of cholesteatoma surgery) in 77 children and 217 adults.

Age (years)	Bone conduction threshold	Air conduction threshold	Air–bone gap
<16	5.8	29.5	24.7
>16	19.1	43.2	24.6

The figures shown are averages for the sample groups. Although the average conductive loss does not differ between the two groups, the overall hearing is better in children because they have a much smaller sensorineural loss.

Technical aspects of ossiculoplasty

There is greater variance in the results of ossicular surgery than the results of other forms of otological surgery. In the last decade, laboratory work using laser Doppler vibrometry and mathematical modelling using finite element analysis has provided insights into the mechanism of the ossicular chain and the optimum techniques for its reconstruction.^{156, 157, 158, 159} **Table 74.17** summarizes some of these findings.

Timing of intervention in children

In all patients, whether adult or child, the decision to offer surgical reconstruction of the eroded ossicular chain should be guided by:

- the likelihood of benefit according to the Belfast rules of thumb or the Glasgow benefit plot;
- the surgeon's own audit of outcomes.

Table 74.17 Guidelines for surgical technique from laboratory results.

Factor	
Adhesions	Adhesions to the promontory have a profoundly adverse effect
Displacement	To prevent displacement and rotation of the prosthesis, ensure secure attachment to stapes head or footplate
Tension	Low tension is best; do not stretch the tympanic membrane
Malleus	Using the malleus handle gives better results
Prosthesis mass	High mass has an adverse effect on high frequencies
Prosthesis stiffness	Low stiffness (e.g. cartilage, polyethylene) has an adverse effect at all frequencies

There are some special considerations about ossicular reconstruction in children. The younger the child, the greater the risk that other features of chronic middle ear inflammation, such as middle ear effusion, may still be present. The adverse effect this may have on surgical repair of the tympanic membrane has been presented above in Elimination of middle ear pathology under Chronic perforation of the tympanic membrane. Clearly such problems may both mask any benefit from surgical reconstruction.

In children some concern has been raised about the use of middle ear implants because data on their long-term effects are not available. If only the patient's own ossicles are to be used then it is important that these should not become involved in the underlying disease. For example, ossicular reconstruction in children with cholesteatoma should not be undertaken until it has been demonstrated that there is no residual disease.

CONCLUSIONS

The term 'chronic otitis media' has become ambiguous through confusion with similar terms and through multiple different classifications but is best considered a pathological term. Chronic otitis media can affect all structures within and adjacent to the temporal bone. Its presence can be confirmed by histological assessment and be inferred from its complications. The causes of chronic otitis media are poorly understood; there is no proven prophylaxis against it.

'Chronic suppurative otitis media' is an historic but useful term. It is defined as the presence of chronic ear discharge in the presence of a chronic tympanic membrane perforation. The duration required to satisfy the term 'chronic' varies from definition to definition.

The prevalence of chronic suppurative otitis media is highest in children in Aboriginal communities in otherwise developed countries and represents a massive public health problem. In nonindigenous communities in developed countries, the prevalence of tympanic membrane perforation is higher in adults than in children. Medical treatment of the symptom of ear discharge in chronic suppurative otitis media is best treated with aural toilet and topical fluoroquinolones.

Below the age of 13 years, the rate of successful tympanic membrane repair diminishes with younger age. The nature of the surgical repair of the tympanic membrane depends on the size of the perforation and the state of the remainder of the tympanic membrane and middle ear cleft. The rate of surgical closure of the tympanic membrane can be over 90 percent in the short to medium term in subspecialist hands. The national average rate in Britain is nearer 65 percent. Personal audit of surgical results is essential to provide the patient with the accurate information on which the decision to proceed or reject surgery will be based.

Pars tensa retraction starts in childhood. Tympanic membrane retraction is associated with progression of disease in one case in six once atrophy occurs. The progression of disease following atrophy of the tympanic membrane is slow, but may result in ossicular erosion or cholesteatoma. Tympanic membrane retraction without atrophy does not progress. Risk factors that accurately identify those cases that will progress to cholesteatoma have not been identified.

Tympanic membrane retraction pocket excision is a surgical procedure which acts as prophylaxis against the development of cholesteatoma. Selection of suitable cases for this procedure remains controversial. Personal audit of surgical results is necessary to inform decision making in the management of tympanic membrane retraction pockets.

Cholesteatoma reaches peak prevalence in the second decade. It is more extensive in children than in adults, but less commonly erodes into important temporal bone structures. In general, surgical treatment of cholesteatoma in children is associated with higher rates of residual and recurrent disease. There are many different surgical techniques that aim to satisfy the conflicting requirements of cholesteatoma surgery. Personal audit of surgical results using multiple long-term outcome measures is necessary to inform decision making in the management of cholesteatoma.

The results of ossicular surgery are influenced by the nature of the ossicular defect, but are also operator dependent, being highly sensitive to tiny variations in position and tension. These results, when measured according to a scale that correlates well with patient satisfaction, are better in children than in adults. This is mainly because the contribution of sensorineural hearing loss in children is less than in adults.

KEY POINTS

- The study and teaching of chronic otitis media has been hindered by multiple, ambiguous definitions of the term.
- In this chapter, chronic otitis media is considered to be a pathological term referring to persistent inflammation of the mucosa and submucosa of the middle ear. It is considered to be complicated by chronic inflammatory changes in the structures comprising and adjacent to the middle ear. According to this model surgical treatment is viewed as correcting these complications, but not materially affecting the underlying chronic otitis media. The model predicts that surgery may be compromised by the ongoing effects of middle ear inflammation and this appears to be particularly true after the treatment of children. Nonetheless, modern management strategies and surgical techniques have progressed a long way in the past two decades and it is now possible to offer treatment outcomes for the complications of chronic otitis media in children which approach those obtained for adults.
- Recent microscopic evidence of biofilms in otitis media has indicated that this mechanism may be important in maintaining chronic ear infections.
- The social basis of the very high rates of chronic suppurative otitis media in some indigenous communities, particularly in children, has been recognized and forms the basis of new health policies, following the failure of medical treatment strategies to impact on this problem.
- Success rates in surgical closure of the tympanic membrane are, in general, low. The British national average successful closure rate is 65 percent. Surgeons with a specialist interest report higher rates of closure.
- Atrophy and retraction of the tympanic membrane is most prevalent in the second decade of life.
- Atrophy of the tympanic membrane ranges from mild through to more severe retraction with fixation of the atrophic segment to the bony walls of the middle ear. Approximately one case in six of tympanic membrane collapse is progressive. In these cases tympanic membrane retraction may become associated with erosion of the ossicles. A small proportion of advanced tympanic membrane retraction pockets progress to become cholesteatoma.

- The only actuarial data concerning long-term results after pars tensa retraction pocket excision in children suggest that the deleterious effects of the underlying pathology remain vigorous; in half of cases, the retraction pocket returns.
- We have only a limited understanding of which collapsed tympanic membranes will progress, so the management of this condition is extremely controversial.
- Cholesteatoma is most prevalent in the second decade of life.
- Children have a higher rate of recurrent cholesteatoma after surgery than adults.
- As a general rule, the more erosion of the ossicular chain the more difficult it is to surgically reconstruct useful hearing.
- Surgery for ossicular erosion, cholesteatoma and tympanic membrane perforation are all difficult and therefore highly operator dependent.
- A highly operator-dependent environment weakens the generalizability of individual prospective randomized studies on surgical treatment.
- Surgeons should be encouraged to carefully audit their own practice to inform themselves (and their patients) about likely outcomes for planned procedures.

Best clinical practice

- ✓ In purulent otorrhoea, topical antibiotics with aural toilet is the most effective method of treatment and quinolones appear to be more effective than other types of antibiotics in resolving otorrhoea. [Grade C]
- ✓ No topical aminoglycoside is officially recognized for use in patients with perforated ears. Any doctor who wishes to offer a medicine containing an aminoglycoside for topical application in a child with a perforated tympanic membrane should inform the patient and the patient's carer, prior to offering the treatment, of a potential risk of imbalance or permanent sensorineural hearing loss. [Grade C]
- ✓ Short-term success rates in surgical closure of the tympanic membrane are lower in very young children. In the longer term, the situation is aggravated by persistence of the effects of chronic otitis media, including middle ear effusion, reperforation and myringitis. The surgeon faced with a young child with a chronic perforated tympanic membrane should consider whether surgical repair would be better delayed. [Grade C]

- ✓ The management of cholesteatoma in children is surgical. The two main principles that underpin good surgery for this condition, thorough extirpation of disease and the preservation of a robust dry ear are difficult to balance, hence tympanomastoid surgery for cholesteatoma in children is particularly challenging. [Grade C]
- ✓ Cholesteatoma in children differs from that in adults in that it more often arises from the pars tensa and it is more commonly extensive. It is more difficult to remove in children and has a greater tendency to recur. [Grade C]
- ✓ Surgeons should be encouraged to carefully audit their own practice to inform themselves (and their patients) about likely outcomes for planned procedures. [Grade D]

Deficiencies in current knowledge and areas for future research

- Real understanding of the aetiology of chronic otitis media is lacking. At present there is considerable interest in the relationship between biofilms and chronic middle ear inflammatory disease. Future developments in this area of research are keenly awaited.
- Further results from the research into management of the social factors that result in high rates of chronic suppurative otitis media in indigenous communities are expected. The long-term outcome of this treatment, as well as how effectively it can be implemented elsewhere, will be of considerable interest.
- Results from studies investigating the role of topical antiseptics in chronic suppurative otitis media should be received soon. Prospective, randomized controlled trials of topical antiseptics against topical quinolones should clarify the treatment of choice for reducing otorrhoea in this disease.
- Steps to improve the national rate of successful tympanoplasty are needed. Improved access through canalplasty seems likely to be rewarding and further research into the benefits of this technique is needed.
- Improved understanding of the factors driving the deterioration of the tympanic membrane from atrophy through retraction to cholesteatoma may improve decision making in this disease.
- The role of the fibre-guided laser in cholesteatoma surgery should be further investigated. The laser offers a new means of accommodating the conflict between disease removal and functional integrity of the ear. There remains the exciting possibility of increased preservation of the ossicular chain with this technique.

- Surgical outcomes for the complications of chronic otitis media are highly dependent on the operator so efforts to promote a wholly evidence-based approach will continue to be bedevilled by lack of generalizability. Nonetheless, there are many aspects of surgery of the tympanic membrane, cholesteatoma and ossicles that could be evaluated with prospective and randomized studies.
- In the absence of high-level evidence, the most effective means of improving decision making for most surgeons will be through recording personal outcomes of surgery. A database of such outcomes will provide the surgeon about his/her success with different strategies for given surgical problems.
- It seems increasingly unlikely that patients will accept advice about the merits of surgical intervention without quantitative information from their prospective surgeon's own practice. Improvements in the collection and awareness of outcome data will be the first step in this direction.

ACKNOWLEDGEMENTS

Thanks to James Robinson for sharing his painstakingly kept database; Francis Lannigan for details concerning the swimming pool trial in Western Australia; Jeffrey Vrabec for sharing the unpublished raw data from his metaanalysis of paediatric tympanoplasty; Manohar Bance for sharing the results of his ossiculoplasty research, not all of which has been published at the time of writing.

SEARCH STRATEGY

The references for this chapter were compiled from a Medline search using the search terms congenital, ear and child. The opinions expressed are largely based on the personal experience of the authors.

INTRODUCTION

The embryology of the ear is complex and congenital anomalies are common. This chapter presents a résumé of the common anomalies and a discussion of the treatment options. Both hearing problems and deformity of the pinna can cause a great deal of distress. High quality surgery can lead to major improvements.

EMBRYOLOGY

A detailed knowledge of the normal embryology of the ear is a prerequisite to understanding the spectrum of congenital deformities that can occur and helps the surgeon predict the probable association between anomalies of the pinna, ear canal, middle and inner ear and facial nerve based on the time of embryological interruption.

Pinna

By the end of the fifth week, five branchial arches are discernable. In a 38-day-old embryo, six hillocks have developed in the mesenchymal tissue of the first (mandibular) and second (hyoid) arch and a process of fusion produces a primitive ear in the 50-day-old embryo. Hillocks 1–3 come from the mandibular arch and 4–6 from the hyoid. [***] The process of accretion is complicated and there is controversy over which hillock produces each part of the ear but Park,¹ after analysis of clinical cases makes a strong case for the theory that hillock 1 produces the anterior portion of the ear lobe, hillock 2 the tragus and hillock 3 the ascending helix. Of the second arch hillocks, 4 and 5 produce the anti-helix and the helix, with 6 contributing to the posterior lobule. This is supported by the arterial supply of the ear where hillocks 1, 2 and 3 correspond to the territory of the superficial temporal artery and hillocks 4, 5 and 6 to the distribution of the posterior auricular artery.¹ [***]

The conchal bowl originates from the first branchial groove. Incomplete fusion of the hillocks may cause clefts and hypergenesis may cause tubercles, tags and polyotia. The normal size of the auricle at birth is 66 percent of the length and 76 percent of the width of an adult ear.² By the age of six, the auricle has attained 90 percent of adult proportions. The pinna develops around the external meatus, which begins to canalize at week 28. The ear initially forms in the neck region and moves upward onto the head by week ten. In many anomalies, this migration is disturbed and the ear remains low set.

Malformation, such as anotia and microtia, are likely to be caused by the disturbance of development at seven to eight weeks gestational age, whereas deformations (lop, cup and prominent ears) are caused by a problem later in the development or by external compression.

External ear canal

The external ear canal arises from the ectoderm of the first branchial cleft, which appears at four weeks and extends medially towards the mesoderm of the first groove (developing tympanic ring) and first branchial pouch (the embryonic middle ear) during the eighth week. The ectoderm of the ear canal is separated from the endoderm of the first branchial pouch by a layer of mesoderm which becomes the middle fibrous layer of the ear drum. The tympanic ring begins ossification at 12 weeks and forms the bony portion of the external auditory canal. At 28 weeks, a core of ectoderm canalizes from medial to lateral and eventually breaks through to communicate with the conchal depression. [****] Failure of canalization or more rarely lack of ectodermal migration can lead to atresia of the external auditory meatus (EAM),³ and partial canalization leads to meatal stenosis (an EAM with a diameter of less than 4 mm). Disruption of normal canalization or ectodermal migration can lead to arrested development of the tympanic ring mesoderm with the formation of a dense atretic bony plate in place of the tympanic membrane, an almost universal finding in canal atresia.

Middle ear and ossicles

The first branchial pouch starts to expand to form the Eustachian tube, middle ear and mastoid between the fourth and sixth weeks, but remains filled with mesenchyme until resorption, ossicular development and expansion of the pharyngeal pouch replaces this tissue.³

The ossicles are developed from the mesoderm of the first and second branchial arches with the exception of the stapes foot plate which also derives tissue from the otic capsule. The first arch derivatives form the head of the malleus and body and short process of the incus, whereas the more caudal structures, the manubrium of the

malleus, long process of the incus and stapes suprastructure arise from the second arch. They start to develop during the fifth week of life. The incudostapedial joint forms during the seventh week. The endoderm of the middle ear cleft develops into the mucosal lining as supporting mesenchymal tissue resorbs, freeing the ossicular chain. [****] Failure of this process leads to a fused incudomalleolar mass which is often attached to the atretic bony plate.

The stapes has two developmental origins. The second arch cartilage forms the suprastructure and tympanic part of the foot plate. The vestibular portion of the foot plate and annular ligament are derived from the otic capsule. The process starts at five weeks and is not completed until 26 weeks. The developing stapedial anlage folds around the stapedial artery and meets the depression (lamina stapedialis) which form independently from the otic capsule. Any structure that interposes (such as a facial nerve or aberrant artery) can adversely effect the development of the oval window.

Ossicular abnormalities are frequently encountered in atresia surgery. They range from near normal development to ossicular fusion and a rudimentary monoblock ossicular mass. If an atretic plate is present, the malleus is always fused to it.⁴ Other abnormalities include absence of the manubrium of the malleus, a shortened long process of the incus, failure of the incus to connect with the stapes and fusion of the incudostapedial joint (ISJ). Stapedial abnormalities are fortunately not as common as other ossicular anomalies⁵ and although stapedial mobility can be hard to assess due to incudomalleolar fixation, in the presence of a reasonably well-developed suprastructure, a mobile foot plate can be expected.

Inner ear

Although the inner ear and labyrinthine windows have a different embryological origin from the middle and outer ear, abnormalities such as failure of the oval or round window to develop or congenital abnormalities of the cochlea, particularly a Mondini malformation can occur. Based on audiometric and polytomographic studies,⁶ 10 percent of patients with atresia will have an inner ear abnormality, usually in the affected ear, but occasionally in the contralateral 'normal' ear. More recent studies using high resolution computed tomography (HRCT) suggest a higher rate of inner ear congenital anomalies affecting between 10 and 47 percent of patients with atresia.^{3,7}

Facial nerve

For the otologist, the ability to predict the course of an aberrant facial nerve in atresia is one of the most important aspects of surgical planning. Satoloff⁸ and

Gulya³ provide a comprehensive review of facial nerve embryology and its practical application, and it is usually possible to deduce the course of the facial nerve by careful analysis of the arrested development⁹ supplemented by HRCT scanning.

The facial nerve first appears as the facio-acoustic primordium, the nerve of the second branchial arch at three weeks. At four to five weeks, the sprouting facial nerve and chorda tympani divide the primitive mesenchyme of the second arch into the stapes, stapedius muscle and posterior middle ear wall precursor. At seven weeks, five branches appear in the parotid bud and by 16 weeks the neural communications with the facial muscles are complete (see also Chapter 80, Facial paralysis in childhood). At this stage the course of the facial nerve is much more anterosuperior than in adults.

At eight weeks, a sulcus develops on the posterior otic capsule (the primitive Fallopian canal) and this first genu is remarkably constant. Dehiscence of the horizontal portion and second genu occurs in 25–55 percent of post-mortem temporal bones,^{8,10} but displacement is much less common. At ten weeks, the vertical (mastoid) segment of the facial nerve is anterolateral to the middle ear (ME) and external auditory canal (EAC). Failure of the tympanic ring and mastoid to develop over the next 16 weeks places the nerve in a more primitive position. The angle at the second genu at ten weeks is 60°, only reaching the more normal angle of 120° by 26 weeks. Failure of the normal separation between the mastoid and temporomandibular joint (TMJ) leads to a more acute angle at the second genu, increasing the risk of dehiscence and inferior displacement over the oval window. In early developmental arrest, the nerve can pass between the oval and round window, passing through the postero-inferior portion of the atretic plate and exiting through the glenoid fossa. In severe cases the nerve or branches may exit just below a rudimentary tragus.¹¹ Other abnormalities include a bifurcating facial nerve and a large chorda tympani containing motor fibres.¹²

EPIDEMIOLOGY AND AETIOLOGY OF EAR DEFORMITY

Epidemiology

Microtia occurs once in every 6000 births. The occurrence is estimated at one in 4000 in the Japanese and as high as one in 1:1200 births in Navajo Indians. In 10 percent of cases, the problem is bilateral. The right side is more commonly affected than the left and males are more often affected than females. The overall frequency of prominent ears in North America is 4.5 percent.^{13,14} Skin tags occur in 0.2 percent of the population. Congenital atresia/microtia can occur sporadically as an isolated congenital anomaly, associated with other anomalies or as part of a

recognized syndrome. In most cases the cause is unknown, but in a minority (15 percent) a genetic or environmental cause (foetal alcohol syndrome, maternal diabetic embryopathy, thalidomide and isotretinoin exposure) can be identified. A small number of familial cases of isolated atresia have been reported with autosomal dominant, recessive and x-linked inheritance. Several pairs of identical twins are identified where only one twin has microtia. This lends support to the theory that an intrauterine event rather than a genetic trigger suppresses ear development. At present, haemorrhage in the region of the stapedia artery at a critical phase is the most likely local cause.¹⁵ Thalidomide was thought to induce this.

Syndromic associations

A syndrome does not infer a genetic cause. Whilst the gene mutation causing mandibular facial dystostosis has been identified¹⁶ and brachio-otorenal syndrome is known to be genetic, hemifacial microsomia is just a constellation of abnormalities that are clinically recognizable but at present regarded as idiopathic with no inherited tendency. The causes are probably pathologically heterogeneous with defective genes, teratogens or vascular anomalies acting singly or collectively to disrupt normal development.^{17,18} Syndromic conditions associated with congenital aural atresia include:

- hemifacial microsomia (HM);
- Treacher Collins;
- brachio-otorenal;
- Sticklers;
- Crouzons;
- Noonan syndrome;
- foetal alcohol syndrome;
- coloboma, heart defects, choanal atresia, developmental and growth retardation, genito-urinary malformations and ear anomalies (CHARGE) (see also Chapter 82, Nasal obstruction in children).

See also Chapter 78, Craniofacial anomalies: genetics and management.

HEMIFACIAL MICROSOMIA OMENS

Hemifacial microsomia (HM) is a spectrum of malformations involving the orbit, mandible, ears, facial nerve and soft tissues of the face occurring in 1 in 5600 births.¹⁷ Most cases are sporadic, but in rare cases there are familial patterns consistent with autosomal dominant or autosomal recessive inheritance. The presence of a twin is thought to make the causal event more likely to occur.¹⁹ It is generally unilateral but bilateral cases occur in 17 percent. There is a prediction for the right ear (58 percent) and males (63 percent).²⁰ Isolated microtia

has been considered a minor form of HM. Facial weakness and hearing loss are the most common functional defects with 86 percent having a conductive hearing loss and 10–16 percent having a sensorineural hearing loss, a feature that is underappreciated (incidence in the general population is 0.001 percent and in other craniofacial syndromes, 3–4 percent). There is little correlation between the severity of the dysmorphic features and hearing loss. Patients with mildly dysmorphic features can have a moderately severe degree of deafness. The five major features (orbital, mandibular, ear, nerve and soft tissue) form the basis for the most comprehensive and clinically useful classification system, the OMENS score.¹⁷ See also Chapter 80, Facial paralysis in childhood and Chapter 78, Craniofacial anomalies: genetics and management.

Mandibular facial dystostosis or Treacher Collins syndrome is a more specific condition caused by an abnormality on chromosome 5 (5q32-33.2).¹⁶ This is an autosomal dominant condition causing a first and second arch malformation. Six percent occur as a sporadic mutation.²¹ The condition is characterized by down-sloping palpebral fissures, coloboma of the eyes, hypoplasia of the mandible and maxilla, cleft palate and microtia with atresia. The incidence is 1 in 50,000 live births. Most have bilateral malformed pinna and aural atresia. It is common for the mastoids and middle ears to be poorly developed and in many patients the middle cranial fossa descends to the level of the superior semicircular canal²² and the jugular bulb protrudes into the small tympanic cavity, making most of these patients unsuitable for middle ear surgery. Most patients have normal inner ear function.

Brachio-oto-renal (BOR) syndrome occurs in 1 in 40,000 children as an autosomal dominant condition. Branchial clefts, fistulae and cysts occur with a malformed pinna and preauricular pits. The syndrome is associated with various renal anomalies. Seventy-five percent of patients with BOR syndrome have a significant hearing loss. Of these, 30 percent are conductive, 20 percent sensorineural and 50 percent mixed.²³ Recent mutational studies in *Drosophila* have shown that gene EYA1 causes the syndrome. The encoded protein or transcriptional activator has been located to chromosome 8 in humans.²⁴ See also Chapter 66, Molecular otology, development of the auditory system and recent advances in genetic manipulation.

Stickler syndrome is another autosomal dominant condition presenting with cleft palate, micrognathia, severe myopia and retinal detachment. Most of the conductive hearing loss is due to Eustachian tube dysfunction secondary to the cleft palate, but ossicular abnormalities may be present. Some cases have a progressive high frequency sensorineural hearing loss. Mutation of the COL2A1 gene on chromosome 12 has been implicated.²³ See also Chapter 66, Molecular otology, development of the auditory system and recent

advances in genetic manipulation and Chapter 78, Craniofacial anomalies: genetics and management.

Crouzon syndrome (craniofacial dystostosis) is an autosomal dominant craniofacial anomaly with a prevalence of 1 in 50,000, but with marked variability of phenotypic expression characterized by craniosynostosis, maxillary hypoplasia and shallow orbits causing proptosis. A conductive hearing loss is present in 50 percent of cases with 13 percent having aural atresia. See also Chapter 78, Craniofacial anomalies: genetics and management.

Noonan syndrome is a craniofacial abnormality associated with short stature, webbed neck and cardiac abnormalities. The incidence is 1 in 25,000 births²⁵ and otological problems consist of low set and posteriorly rotated ears, infolding of the helix and a 10–15 percent incidence of sensorineural hearing loss.

Foetal alcohol syndrome is the leading cause of mental retardation in the western world²⁶ with an incidence of 2 in 1000 live births. Midfacial hypoplasia is common and the condition accounts for 10 percent of children with Pierre Robin sequence. Otological features are posteriorly rotated ears with a poorly formed concha and mixed hearing loss.

The acronym 'CHARGE' describes a nonrandom clustering of malformations and includes coloboma, heart defects, choanal atresia, developmental and growth retardation, genito-urinary malformations and ear anomalies. The head and neck anomalies, in addition to choanal atresia, include external ear abnormalities in 68 percent of cases, congenital middle ear ossicular anomalies in 10 percent and sensorineural hearing loss in 8 percent. Facial nerve dysfunction occurs in 38 percent and was found to be a statistically significant predictor of profound hearing loss which was not true of the severity of the external ear deformity.²⁷

THE RANGE AND TREATMENT OF EXTERNAL EAR DEFORMITIES

What is normal?

It is important to have a sense of the normal ear in order to fully appreciate the concerns of patients with abnormalities of ear size, position and slope (Figure 75.1). The average adult female ear is 59 mm tall and the average male ear 63 mm tall. In boys, the ear length is 48 mm at six months increasing to 55 mm at five years and 59 mm at ten years. The values are a little reduced for girls. The ear is thus almost fully grown at ten years. Thereafter, it seems to remain much the same size until the age of 60 when it gradually enlarges, particularly the lobe (Figure 75.2). The average adult ear protrudes 19 mm from the mastoid skin. The long axis of the ear slopes backwards in line with the slope of the nose. The

Figure 75.1 The external ear.

Figure 75.2 The ear often enlarges with age.

ear lies between the level of the eyebrow and a line a few millimetres beneath the nasal columella. The distance from the lateral canthus of the eye to the front of the ear is just over the length of the ear.

A number of patients are extremely sensitive about ears that are excessively large, protruding or which slope forwards. The variety of ear deformity is wide.

Tags

Preauricular skin tags are very common (Figure 75.3a). Sometimes the lesion involves only skin but usually the tag contains a long tail of cartilage extending into the cheek (Figure 75.3b). It is commonplace to ligate

Figure 75.3 (a) A patient presents with preauricular skin tags. (b) When removed, they are often seen to have long cartilage stalks.

preauricular skin tags in the neonatal period. A new technique is to apply a Liga clip – this is quick and easy to do and a few days later the tag drops off.

Tags with a substantial cartilage core are best treated by elective excision of the skin tag and cartilage spindle under general anaesthetic. A vertical ellipse is recommended.

Mirror ear or polyotia

Rarely, persistent preauricular tissues are so large that they resemble an extra ear and the term 'polyotia' is used. The 'second' ear can appear as a mirror image folded forward and lying on the posterior cheek, and the term mirror ear is also applied (Figure 75.4a). It is recommended that skin is peeled off the extra-auricular tissue and protruding cartilage remnants are trimmed. The trimmed cartilage fragments are packed into the anterior conchal hollow and then the skin of the extra ear is redraped to give the cheek a flatter shape (Figure 75.4b).²⁸

Figure 75.4 (a) Polyotia or mirror ear; (b) postoperative view.

Pits and sinuses

Preauricular sinuses can be difficult to excise and may recur after treatment (Figure 75.5). Very occasionally, the sinuses track deeply near to the facial nerve. They are often bilateral and frequently asymptomatic. However, if recurrent infections occur which fail to settle with anti-staphylococcal antibiotics, surgical excision is appropriate. Although most are simple branching sinuses they can pass close to the facial nerve and the use of a microscope or loupes is a great help. It is advisable to use active facial nerve monitoring and avoid local anaesthetic infiltration.

Figure 75.5 An infected preauricular sinus.

Abnormal folds (Stahl's bar)

Abnormal folding of the ear is common (Figure 75.6a). A Stahl's bar or third crus is a frequent finding (Figure 75.6b). In a small number of cases, the upper pole of the ear flops over and here the term 'lop ear' is used. In some ears, a kink of the helical rim or abnormal fusion of the helical rim to the antihelical fold is observed. In some patients the whole ear appears collapsed vertically to give an ear of reduced height. Stahl's bar is easily and temporarily corrected by finger pressure, but surgical correction often turns out to be difficult to execute.

Attempts to reshape the cartilage by either scoring or tie-bar type tethering sutures are rarely successful and a splint (Figure 75.6c) gives a better result. The technique in which the offending cartilage kink is excised as a disc, turned over and through 90° so that the trough is in line with the scaphal hollow, is attractive but not usually wholly successful. A direct wedge excision of the Stahl's bar (skin and cartilage) is a more reliable technique. As the cut edges of the helical rim are sutured together it tends to gain a more normal curl, and although the ear is made smaller it is usually much more attractive.²⁹

Figure 75.6 (a) Abnormal folds; (b and c) Stahl's bar pre- and post correction with a splint.

Prominent ('bat') ears

Prominent ears are sometimes present at birth (61 percent), while other cases become obvious as the infant

head shape changes (Figure 75.7a).³⁰ The condition is not viewed as a deformity in all cultures. The prominence is usually due to an absent antihelical fold but, in some cases, the conchal bowl is excessively deep. A prominent lobe or antitragus is less common. A grading scale for

© Hodder Arnold / Scott-Brown 7E

Figure 75.7 (a) Prominent (bat) ear; (b) a prominent ear which lacks an antehelical fold.

prominent ears has been put forward by Graham and Gault,³¹ which, in addition to the above features, factors in elasticity and memory of the cartilage. Digital pressure on the relevant part of the ear determines the cause for prominence and gauges the strength of the cartilage. It is recommended that surgery to set back ears be delayed until after the age of five years. Prior to this, the cartilage is especially soft and efforts to reshape it may instead cause irregularity.

Sometimes parents (quite understandably) want prominent ears corrected when the child (equally understandably) is reluctant to have the operation. It is safest in such a situation to put the wishes of the child first. Children who are teased are usually willing to have surgery. Sometimes the need to wear hair up in a ballet class, for example, will prompt a request for surgery.

It is essential to discuss preoperatively the desired position of the ears. Some patients want only a gentle change whilst, for others, only ears which are flat to the side of the head are acceptable.

No two prominent ears are the same. The most common problem is an inadequate antihelical fold (Figure 75.7b). This can cause the ear to protrude at

right angles to the mastoid skin. In other ears the conchal bowl is excessively deep, but the antihelical fold is normal. During correction, some ears will need additional attention to a protruding lobe or isolated protrusion of the upper pole alone. In some ears, the reshaping is specifically intended to improve hearing aid retention, and in these, space must be left for the device.

Surgical techniques to remould the cartilage include anterior scoring (Figure 75.8),³² reshaping of the curves by the use of posterior sutures (to emphasize the antihelical fold or to setback the concha)³³ and excision techniques to set back the concha. It is not conventional to rely on skin excision alone to hold back the ear, since this may increase the risk of hypertrophic scarring. Correction of bat ears is challenging surgery and unsatisfactory results can give rise to litigation. It is essential that surgeons who undertake this sort of work are adequately trained and carefully audit their outcomes. Inadequate set back, abnormal shape or folding, keloid scars and significant tissue destruction can cause patients to seek legal redress (Figure 75.9). It is important to record that adequate warning of potential problems has been given. Vigilance and prompt treatment of any problems is advised.

Collapsed ears

In a number of patients, the helical rim is adequate but the scaphal hollow is folded backwards to rest on the conchal hollow. The height and shape of the ear is readily improved by undoing soft tissue tethering between the scaphal and conchal cartilages and splinting these structures apart with a cartilage graft. The conchal hollow is a suitable donor site for such grafts.

Folded-over helical rim

When the helical rim cartilage is sharply folded over to provide a double layer covered in a single skin envelope, the ear looks pinched. To correct this, the folded-over

Figure 75.9 (a) An ear kink after prominent ear surgery; (b) the thin indented rim cartilage is reinforced with a cartilage graft and the rim is splinted; (c) the final result.

cartilage (Noonan syndrome, described under Hemifacial microsomia) is excised and then repositioned behind the scaphal hollow to open up the upper pole.

Lop ears

To support a lop ear, 'Mustarde'-type sutures can be used to create a U-shaped cartilage prop at the site of the missing upper antihelical fold.³³ As reinforcement, it is recommended that the ear be hitched to the mastoid fascia (**Figure 75.10**).³⁴

'Bumps' and clefts

A bump on the helical rim is a common finding, often referred to as a 'Darwin's tubercle'. This swelling lies at the point at which hillocks 3 and 4 normally fuse.

A cleft of the ear lobe is not a common finding (**Figure 75.11**). In some patients, it is a groove or notch due to poor fusion of hillocks 6 and 1. In others, a significant portion of the lobe is missing due to absence of hillock 6.

The standard cleft of the ear lobe leaves a notch. The anterior fragment is often more medial than the posterior fragment, such that the lobe components lie in different planes. It is possible to raise interposing skin flaps from the notch and to realign the deep tissues with a fine suture. Skin flaps are then redraped and trimmed over the new lobe to resurface it.

In some cases a lobe may be underdeveloped or absent. Such lobes must be rebuilt around a cartilage framework; a disc of conchal cartilage usually suffices.

A partial cleft may interrupt the smooth helical rim as an oblique notch. After peeling the skin off, the

© Hodder Arnold / Scott-Brown 7E

Figure 75.10 Lop ear.

cartilage can be divided in a zig-zag fashion and the leaves resutured to expand the arch of the ear.

Another variation is the absent helical rim.

Macrotia

Excessively large ears are a common cause of teasing. Various components of the ear may be overlarge. In a

© Hodder Arnold / Scott-Brown 7E

Figure 75.11 A congenital cleft of the ear lobe.

normal ear, the upper pole, conchal hollow and lobe take up an equal amount of the height of the ear, splitting it into thirds. In many cases of macrotia, the scaphal hollow is too big, causing the ear to appear top-heavy (**Figure 75.12**). In others, the lobe is too big, so that the ear appears bottom-heavy.

To reduce an excessively large upper ear, it is recommended that an anterior crescent of skin and cartilage be removed from the scaphal hollow of the ear.³⁵ The helical rim is then advanced around the now smaller ear, preserving the posterior skin to ensure blood supply to the rim. As the root of the helix is approached, spare rim skin and cartilage is trimmed. The cartilage is sutured with fine absorbable sutures. The scars are hidden in the curve of the helical rim and are usually inconspicuous. To reduce an oversized lobe, a wedge of tissue is removed.

Cup ears

In these ears the helical rim is constricted to give a prominent, cone-shaped ear. This is particularly difficult to correct. The constricted rim of a cup ear must be expanded in order to allow it to flatten. A number of techniques have been described. The cartilage can be incised in a zig-zag fashion to expand it once the skin has been peeled off the rim. An alternative is to make a series of radial incisions and to splint them open with a cartilage graft. Another technique is the use of a V-Y plasty at the root of the helix combined with undermining of adjacent skin. Where the ear is severely constricted (conchal-type microtia) a formal reconstruction using a carved costal cartilage framework is advised.

© Hodder Arnold / Scott-Brown 7E

Figure 75.12 Macrotia – the scaphal hollow is overlarge.

Cryptotia ('the hidden ear')

Sometimes, only the lower two-thirds of an ear is visible and the upper auricular sulcus seems lost (**Figure 75.13**). When the ear is gently pulled away from the side of the head, the upper pole cartilage becomes evident, having been hidden beneath scalp skin. The upper pole is excessively tethered and the lower pole is prominent. To attempt an early, nonsurgical correction, a small Ear BuddiesTM splint should be applied as soon as possible after birth to create the upper sulcus. Later, surgical treatment requires the insertion of a skin graft or local flap to release the tethered portion of the ear. The upper auricular sulcus must be recreated with flaps or skin grafts. A simple technique is to widely release the ear by dividing all the fascia and muscles responsible for the tethering and to rotate a superiorly hinged pedicled flap of post-auricular skin from the lower pole into the resulting defect. Occasionally, a revision procedure is required.

Positional problems

An ear which slopes in line with the nose gives a harmonious appearance to the head. Some ears may be too low set. They can often be hitched upwards

Figure 75.13 In cryptotia, the upper ear cartilage is buried beneath the scalp.

(auropexy). Sometimes the axis of the ear may be abnormal, such that patients complain about their ears, but are unsure of what is wrong. These ears are usually excessively vertical and it is possible with conchomastoid sutures to adjust the slope (**Figure 75.14**).

Unusual malformations

Vascular malformations including capillary haemangioma and port wine stain can involve the ear. Hypertrophy of the lobe is common in patients in whom a giant naevus involves the ear. In patients with neurofibromatosis, the ear is often enlarged and malpositioned. Lymphangiomas can present on the ear and sometimes occlude the meatus (**Figure 75.15**).

Splintage

The cartilage of the newborn ear is extremely soft and pliable, possibly due to the influence of circulating maternal oestrogen. In a number of ear deformities in which there is a normal amount of skin and cartilage but the ear is abnormally shaped or prominent, splintage can be curative if performed soon after birth.³⁶ This technique is applicable to prominent ears, Stahl's bars, lop ears,

© Hodder Arnold / Scott-Brown 7E

Figure 75.15 Macrotia due to a resolving haemangioma.

cryptotia and kinks of the rim (**Figure 75.16**). It has no role in treating microtia.

It is several weeks before the ear cartilage begins to harden and ideally splintage should be started in the first few days of life. At this stage the cartilage is easily remoulded, the sweat glands are poorly developed so that the tapes which hold the splint in place stick well, and the child moves its head little, and does not reach up to the ears to dislodge or pick at the splints.

Flexible wire splints totally encased in silicone are now commercially available for parents themselves to apply to their child (**Ear Buddies**). For prominence, rim kinks, Stahl's bar and other abnormal folds, the splints are taped into the scaphal hollow of the ear and then the ear is taped back to the side of the head. The splint exerts

© Hodder Arnold / Scott-Brown 7E

Figure 75.16 A splint *in situ*.

pressure on the scaphal hollow of the ear and emphasizes the antihelical fold and the helical rim. Simply taping the ear back without the splint *in situ* does little to effect an improvement and risks distortion of the rim of the ear. The splint is used in the upper auricular sulcus to correct cryptotia.

In the newborn, splintage for one to two weeks is all that is necessary, whereas in older children (up to six months of age) the splints should be used for several months. If the parents are not diligent in applying the splint then a good correction is less likely. By contrast, some persistent parents achieve a worthwhile correction in children as old as one year. Compliance is increased by the simple expedient of an attractive, though purely cosmetic headband, which hides the tapes and splint on the affected ear or ears from prying eyes.

Early splintage may improve ear shape without the need for later surgery or anaesthetic. Splintage has the additional advantage of preventing presurgery teasing. It is not yet a widespread practice, despite a number of reports which show neonatal splintage of misshapen ears to be of benefit, cheap and safe.³⁷ Nevertheless, it is clear that the future treatment of such deformities lies in this direction.³⁸

MAJOR CONGENITAL MALFORMATIONS – MICROTIA AND ATRESIA

Classification of microtia

There is great variety in the shape of underdeveloped ears. Total anotia is rare; there is no ear structure and a very low hairline (Figure 75.17). The standard microtia patient has a small dependent lobe hanging beneath a cartilage nubbin (Figure 75.18a). In a small number of patients, a narrow strip of normal skin separates two small ear remnants (Figure 75.18b). It is probable that one of these remnants comes from the first and the other from the second branchial arch, which have failed to fuse. Patients in this group usually have facial nerve weakness on the affected side. The facial nerve is prone to damage

Figure 75.18 (a) Standard microtia; (b) two remnant microtia.

during reconstructive surgery, probably because it runs a very superficial course.

Other variations of microtia include the conchal type (Figure 75.19) in which the tragus and a primitive external auditory meatus are present. The term 'constricted ear' or 'cup ear' is used for those cases in which a considerable amount of ear tissue is present. In many of these, when the ear is unfolded, there is a considerable structural defect in the upper pole.

Various classification systems for grades of microtia and atresia have been proposed over the years. All have their merits, but those that reflect the degree of surgical complexity and potential success useful. Although there is a recognizable correlation between the degree of microtia and severity of atresia and facial nerve anomalies, this can only be partially predicted from the type of atresia, and trying to impose a unified classification system underestimates the

Figure 75.19 A conchal-type microtia.

embryological complexity and diversity of this group. Careful analysis in each case of clinical, audiological and radiological criteria is essential if the patient is to receive the best advice and treatment. Marx's classification of the external ear in 1926³⁹ proposed four descriptive groups (Table 75.1) and has formed the basis of most subsequent systems.

A very detailed classification was suggested by Weerda,⁴⁰ that incorporated a surgical plan for each type of defect, but there are valid differences of opinion regarding which type of procedures are appropriate for a particular degree of microtia and a broader classification has generally been accepted. Aguilar and Jahrsdoerfer⁴¹ amended the Marx grading system (Table 75.2), which enabled a surgeon to categorize the auricular deformity easily. Grade I, i.e. a smaller but essentially normal ear, needs no correction. Grade II and III deformities can be treated by a variety of surgical techniques described below.

Classification of atresia

Congenital aural atresia also represents a failure of embryological development but over a longer potential time-frame than auricular deformities. Although the severity of microtia has been shown to correlate with the degree of hearing loss⁴² and middle ear development⁴³ up to 10 percent of atresias occur in isolation and minor auricular abnormalities carry a risk factor for middle ear anomalies. There is also an increased risk (10–25 percent) of contralateral congenital conductive hearing loss in unilateral microtia/atresia.⁹

Table 75.1 Descriptive classification of auricular defects proposed by Marx.

Group	Description
Grade I	The auricle is abnormal; different structures of each part of the ear may be recognizable
Grade II	The auricle is abnormal, parts of the ear are not recognizable
Grade III	Very small auricular tag is present
Grade IV	Anotia

Reprinted from Ref. 39, with permission.

Table 75.2 Classification of congenital deformities.

Group	Description
Grade I	Any normal ear that is simply smaller in size in any given dimension
Grade II	An ear with structural deficiencies, such as absent scapha, absent lobule, broadened helical rim, missing helix, missing conchal bowl or missing anti-helical fold
Grade III	An ear exhibiting the classic 'peanut' deformity with no recognizable structures present, anotia

Adapted from Ref. 41, with permission.

A detailed review of the major classifications of congenital atresia is presented by Declan *et al.*⁴⁴ From a surgical point of view, the anatomical classification of Altman⁴⁵ and its later modification by Marquet⁴⁶ and Cremers *et al.*⁴⁷ is comprehensive, user-friendly and useful for predicting those patients who might benefit from reconstructive surgery (Table 75.3).

Marquet subdivided moderate type II depending on the course of the facial nerve in its third segment, the morphology of the atretic plate, the presence of a tympanic bone and the distance between the glenoid cavity and the anterior surface of the mastoid tip. Surgical outcome was highly related to the proposed classification.⁴⁶

In type IIa, the course of the facial nerve is normal in the third segment. The tympanic bone is hypoplastic, but present with an upper part formed by the squamosal bone and an inferior part from the tympanic bone and extending laterally to the scutum. The distance between the temporomandibular joint and mastoid tip is normal.

In type IIb, the facial nerve is more anteriorly placed in the third segment. The tympanic bone is almost absent and the atretic plate, formed by the squamous bone superiorly and by a length of bone inferiorly extending from the otic capsule but never lateral to the scutum. In between these is often a fibrous ridge containing the facial nerve. A hypoplastic Reichart's cartilage may be present and the distance between the glenoid cavity and mastoid is significantly reduced.

Table 75.3 Classification of aural atresia.

Group	Description
Grade I	The tympanic membrane is still present but hypoplastic. The tympanic bone is normal or hypoplastic. Various types of ossicular malformation have been described, but the stapes is usually mobile
Grade II	An atretic plate is present. The tympanic bone is hypoplastic or absent. The course of the facial nerve may be abnormal. The tympanic cavity is within normal limits
Grade III	The above abnormalities may be found with a severely hypoplastic tympanic cavity

After Marquet⁴⁶ and Cremers *et al.*⁴⁷

Cremers *et al.*⁴⁷ introduced a further subclassification of type II, again related to surgical outcome. In type IIa they place patients who had only partial bony atresia where a fistulous track could be found that connected with the rudimentary tympanic membrane. In type IIb, there is total bony atresia over the full length of the canal.

Attempts have been made to correlate the degree of auricular malformation and atresia into a single unified classification system, but some clarity and clinical usefulness is lost in the amalgamation. There is an interdependence between the two conditions embryologically, audiotologically and when planning treatment, but the factors that influence cosmetic intervention are very different from those that determine the most appropriate treatment for the hearing loss.

Many of the parameters of atresia that determine the potential for surgical success or suggest caution can be defined with HRCT scanning. In 1992, Jahrsdoefer *et al.*⁴⁸ proposed a scoring system for the selection of patients with congenital aural atresia using a ten-point scale based on CT scan elements and the appearances of the external ear (Table 75.4). They reported that 82 percent of patients graded 8–10 achieved a postoperative speech reception threshold (SRT) of 15–25 dB. This system has been validated by several investigators.⁴⁸

A subsequent report⁴³ found that the grade of microtia correlated with the Jahrsdoefer CT grade for aural atresia. Grade I averages 8.5, grade II 7.2 and grade III 5.9. Patients with syndromes involving craniofacial malformations, including Treacher Collins, Goldenhar syndrome, Crouzon and Pierre Robin are considered poor surgical candidates for atresia repair.^{21, 49}

Principles of treatment, discussing the options and the role of the congenital ear team

The realization that their child has a congenital deformity of the ear is inevitably traumatic for parents. They need high quality information and reassurance as early as

possible to reduce apprehension and a commonly felt sense of guilt. There is often a sense of frantic urgency for corrective surgery. This requires thoughtful and realistic parental counselling from all members of the team. Reassurance if appropriate that this is not an inherited condition nor related to any specific event during pregnancy always helps, as does a comprehensible explanation of the condition in terms that the parents can fully understand.

A positive approach will help the child develop a more self-confident attitude to the ‘deformity’. One has to be careful before recommending an irreversible course of action. The two principal surgical approaches – autogenous reconstruction of the residual structures and the use of a prosthetic implant or a bone-anchored hearing aid (BAHA) are complementary rather than competing modalities. If the patient and parents are fully informed, the individual decision becomes much more straightforward. Anyone who has worked in this field will have seen adults who strongly resent having been put through multiple operations as a young child with only limited or no long-term benefit.

Audiologists, geneticists, otologists and plastic surgeons are essential members of the congenital ear team. Psychologists and social workers help the family come to terms with the condition. One of the main functions of the team is to act as an information centre so that the family understand all of the options and have an appreciation of the timescale involved.

Whilst there are psychological reasons to intervene early, particularly in more severe cases of microtia, a more conservative approach allows the child time to make a more mature informed decision. This process of education is at the centre of any congenital ear programme. True informed consent means discussing both the advantages and disadvantages of each treatment option. We insist that each family meets children who have completed treatment, both with reconstructive

surgery and with implant-retained prostheses and BAHAs if appropriate. Half an hour with such a family is worth more than any number of consultations with the surgeon.

To achieve consistently good results, patients need to be referred to a specialist unit. There is no room for the occasional operator and very powerful arguments for establishing a number of regional treatment centres.

If ever there was a need for a partnership between patient/family and a surgical team, this is it. Decisions taken with or on behalf of the child will have lifelong implications. No single treatment is ideal, all involve compromise and choice and there is always a third option to do nothing. Parents need to understand that even if there is an associated atresia, the underlying cochlea function will usually be normal. If unilateral then the hearing in the unaffected ear is very likely to be normal and their child's speech and educational development will not be affected.

In bilateral atresia, the principles of bone conduction hearing aids need to be carefully explained, again emphasizing that 'normal' hearing and development are to be expected. The audiologists are involved from the first consultation and reinforce all this information with appropriate testing and hearing aid provision.

The parents' main concern with microtia is inevitably cosmetic. They need to know that there have been significant advances over the last 15 years and that these will continue in the future. The essential principles of autogenous reconstruction and of an implant-retained prosthesis are explained together with the very definite third option of doing nothing. Although many children do want surgical correction, a significant minority are happy to defer treatment or make a conscious decision not to correct their microtia, particularly if they have a well-developed lobule in the correct position which gives a good impression of symmetry when the patient is first seen. This is especially true for girls and for boys when fashion dictates that they should have longer hair.

The key factor in these early consultations is to inform the family as fully as possible about the condition, the potential for hearing and the options for cosmetic correction in the future. Most children and parents are reassured to know that something can be done, even although this may be many years in the future, and then relax into a more open bonding relationship with their child which helps to develop his or her self-confidence. There are inevitably difficult times when starting or changing schools. Some children yearn for ear reconstruction and the benefits in terms of self-esteem are well established.⁵⁰ In a number of children, bedwetting, truancy and poor concentration at school have resolved when an ear deformity is corrected.

We spend a great deal of time talking to children, and arrange meetings with families whose children have completed autogenous reconstruction and implantation surgery, preferably without a doctor being present. If they

wish to consider osseointegration, we use computer-generated images (Adobe® Photoshop®)⁵¹ to show precisely what they would look like with the remnant ear removed and with the abutments and gold bar in place and with a prosthetic ear attached. Only when we are sure that they are fully informed do we proceed and a significant number of patients elect to have no treatment at this time in the knowledge that they can change their mind at any stage in the future. The results of autogenous reconstruction have improved due to the dedicated work of a few highly skilled surgeons who have modified and refined the technique. Brent, Nagata, Park, Aguilia, Firmin, Weerda and Gault all achieve remarkable results, but it must be recognized that they are superspecialists performing complex multi-stage operations and there will be relatively few centres in any country where work of this high standard can be routinely achieved.^{20, 52, 53, 54, 55}

Ear reconstruction for a standard microtia case is carried out in two stages. At the first operation, an ear-shaped framework is carved from costal cartilage and is placed beneath the non-hair-bearing mastoid skin. Suction drains are used to coapt the skin and thus the framework detail shows through. Tissue from the microtia remnant is repositioned to form a lobe (**Figure 75.20a and b**).

At the second operation six months later, the reconstructed ear is released and held in normal projection with a small cartilage wedge (**Figure 75.20c**). It is very important that the ear is in the ideal position and, in low hair cases, the framework is covered with a temporoparietal fascial flap and skin graft (**Figure 75.21**).

In the past, many operations did not achieve the desired results and left the patient feeling resentful that they had been put through multiple operations at a young age without their consent. Many have subsequently had an implant-retained prosthesis and felt it has been a marked improvement. However, although an implant-retained artificial ear does provide a visually normal ear, virtually identical to the other side with secure attachment to a stable percutaneous implant site in the majority of cases, there are disadvantages. Percutaneous implantation requires subcutaneous tissue reduction that effectively excludes any future autogenous reconstruction. The remnant pinna, particularly the lobule, has to be removed if an ideal result is to be achieved. The percutaneous site has to last for the rest of the child's life, with a replacement prosthesis every 18 months. Life-long commitment to cleaning the percutaneous site (similar to looking after teeth) is also a prerequisite.

The **advantages** are a **very realistic ear** with all the three-dimensional intricacies of a normal pinna and a consequent increase in the patient's self-confidence. Despite 15 years of experience of this technique, in over 40 patients, we still regard autogenous reconstruction as the treatment of first choice, reserving implant surgery for

© Hodder Arnold / Scott-Brown 7E

Figure 75.20 (a) A standard microtia deformity; (b) the framework inserted, suction applied. (c) The final result.

children who make a very conscious decision not to have reconstruction or those referred to us following unsatisfactory plastic surgery.

MICROTIA AND ANOTIA

Treatment for microtia is not essential and some patients will not seek treatment. The surgical options are autogenous reconstruction or a bone-anchored prosthesis. Patients with anotia usually have a low hairline and also require lobe reconstruction.

The gold standard of ear reconstruction is an ear of carved autogenous costal cartilage. Results have improved

© Hodder Arnold / Scott-Brown 7E

Figure 75.21 In this microtia case, the hair line is very low.

enormously in recent years.⁵⁶ The cartilage framework is placed beneath the mastoid skin and suction drains are used to coapt the skin onto it. Local skin can also be draped over other frameworks, such as porous polyethylene and silastic ear shapes. Although their use saves a donor site scar, these nonautogenous materials are currently more prone to infection in the long term.⁵⁷

It is important to stress that autogenous reconstruction is best carried out on previously unoperated sites, as previous surgery can remove valuable skin and causes scars that tend to interfere with blood supply to the skin envelope. It is not uncommon for well-meaning surgeons to perform interim procedures, such as lobe or lop setback, to make the ear look a little better until the child is old enough for a formal reconstruction without realizing that they are compromising the final result.

Autogenous tissue reconstruction is best delayed until the child is ten years of age. By this time, an adequate amount of chest cartilage is available to create a good three-dimensional framework and the risk of chest deformity after harvest is minimal. Prior to this, the ear shape is sometimes difficult to construct because the floating rib is too short to make a complete helical rim or because the pieces that form the base plate are of inadequate thickness to bear the carved detail.

There is in theory no upper age limit to autogenous ear reconstruction and some children who are fearful of surgery at an early age can wait until they feel able to cope. Other children who are the victims of teasing may wish to have the surgery carried out as early as possible,

but surgery prior to the age of seven years may compromise the shape of the framework. If a bone-anchored prosthesis is to be used, then the mastoid bone needs to be of adequate thickness to accept the fixtures. Again, the chance of successful surgery increases with age.

Reconstruction of the microtic ear is technically exacting and only with experience and great attention to detail are realistic results achieved. A framework of costal cartilage is carved and then draped with non-hair-bearing skin. The primitive lobe is repositioned to blend with the framework, a tragus is created and then the reconstructed ear is released from the side of the head to create a post-auricular sulcus. In unilateral cases, a map of the opposite normal ear is made using blank x-ray film (the template). In bilateral cases, it is helpful to ask a relative to act as a model for a template. The design is sketched on to this clear material with a felt tip pen, and the outline is cut out, together with holes for the scaphal hollow and triangular fossa.

With the template positioned on to the side of the head to give a symmetrical appearance, it can be seen whether the lobe will need to be lowered, raised or set back during the reconstruction. In some patients the length of the head (from front to back) on the side of the microtia is reduced and some adjustment of the distances from lateral canthus to ear will be required to give an optimal result. Various techniques are described,^{20, 52} but it must be emphasized that this is exacting surgery and few centres can offer consistently good results.

Implant-retained prosthesis

Surgery for establishing percutaneous fixtures for a prosthetic ear is considerably more complex than for a BAHA. Ideally there should be 3 mm of cortical bone in the optimal position for two abutments. Bone thickness can be measured by HRCT. It is usually possible to find adequate bone in the region of the suprameatal crest where there is a triangle of dense bone between the middle cranial fossa and middle ear cleft, but the mastoid is often poorly developed, which makes it difficult to place the inferior implant at least 2 cm from the superior fixture. If the mastoid has developed, the position of the air cells is unpredictable and the lower fixture may have to be placed anteriorly where the mastoid is shelving medially or posterior towards the lateral sinus.

The cortical bone in children is 'softer' than adults and a lower torque setting is used (20–30 Ncm). If the bone is very thin, the implant can be inserted using the hand-held torque wrench. We always try to use a 4-mm fixture, but if there is less than 2 mm of cortical bone, the flange is left 1 mm above the bone surface and covered with bone dust under a periosteal graft or a Gore-Tex[®] cover, which is known to stimulate new bone formation.⁵⁸

A two-stage procedure is used in children with an interval of four months in an ideal case (4 mm of bone) or six months if one of the above techniques has been used. The main reason is to ensure that the implants are osseointegrated before making the irreversible decision to remove the remnant pinna or reduce the soft tissue.

The importance of subcutaneous tissue reduction so that the epidermis lies on the periosteum for at least 1 cm around the implant cannot be overemphasized. Children show a remarkable capacity for subcutaneous tissue regeneration and inadequate removal leads to mobile skin around the implant with subsequent infection and an unstable percutaneous site.

It is also important to ensure that the abutments are long enough to allow the base plate of the prosthesis to clip on to the gold bar and still maintain an adequate air space around the abutment, which also facilitates easier cleaning. The family must understand that a long-term commitment to the care of the abutments and prosthesis is essential.

With careful patient selection and meticulous attention to surgical detail, this technique offers a remarkably life-like, secure prosthesis and many patients' lives have been transformed. Compared to autogenous reconstruction, the surgery is relatively simple, predictable and carries a high rate of success (94 percent).⁵⁹ There are no donor site scars and the patient only stays in hospital for two days. The downside is that this is still an artificial ear and precludes future autogenous reconstruction. The patient is committed to the care of the implant for life and requires a new prosthesis every 18 months. Whilst the skill of the surgeon is important, the technique is useless without a talented prosthetic expert.

We are cautious about recommending a percutaneous implant in children with congenital heart disease because of the risk of endocarditis.^{60, 61, 62}

ASSESSMENT AND MANAGEMENT OF THE CHILD WITH AURAL ATRESIA

History and examination

Most patients who attend our congenital ear clinic have microtia as well as atresia, but 15 percent present with isolated atresia. Fortunately, unilateral cases are far more common than bilateral which only account for 20 percent. As noted, the condition is more common in males (63 percent) and on the right side (58 percent).²⁰ It is important to understand that 10 percent of children with a unilateral atresia will have a congenital conductive hearing loss in the contralateral 'normal' ear and 5 percent may have an associated sensorineural hearing loss. Microtia/atresia may occur as an isolated anomaly or associated with other malformations. A detailed general paediatric history and examination are required to establish a syndromic diagnosis, not just of the

craniofacial region but of other organ systems particularly the spine and genitourinary system. Exposure to medicines^{63, 64} or infection during pregnancy, amniocentesis or chorionic villous biopsy-threatened abortions or trauma may be relevant together with any family history of similar anomalies or deafness. A general assessment of the physical and mental milestones is made.

The grade of microtia is recorded with particular attention to anterior-inferior displacement of the ears, development of the mastoid tip and the distance between this structure and the TMJ. Evidence of hemifacial microsomia is recorded. The eyes and orbits are examined and the facial nerve function assessed. The external canal is graded as narrow, stenotic (i.e. less than 4 mm), blind ending or atretic. The majority of patients with atresia/microtia have an ipsilateral palatal weakness. The degree of atresia, failure of the tympanic ring to develop as determined by the distance between the TMJ and the mastoid, mastoid size and antero-inferior displacement of the ear, are all clinical features that help predict a potentially aberrant facial nerve.

Audiological investigations

This condition should automatically place the child on a high-risk register for sensorineural hearing loss even if unilateral. Although the majority of children have normal cochlea function even minor congenital anomalies of the middle ear can cause a 40–60 dB hearing loss. Age-appropriate audiological investigations determine the presence or absence of normal cochlea function. If normal hearing can be demonstrated in unilateral cases, no further treatment is necessary at this stage. In bilateral cases or where doubt remains, an appropriate hearing aid is fitted.

The BAHA[®] Softband has been particularly useful, but we use a variety of techniques including a transducer held in a sweatband, a standard paediatric bone conductor hearing aid (BCHA) on a headspring and a BAHA on a headband. Children with cranial synostosis have proved difficult to fit with a conventional BCHA after the age of 18 months and we now routinely use the BAHA[®] Softband. Air conduction (AC) aids are also used whenever possible. All children with atresia have problems localizing sound and we emphasize how important it is to instil the practice of stopping and looking carefully in both directions before crossing roads, as there is an increased risk of road traffic accidents in these children.

Imaging

High resolution computed tomography scanning, which forms the foundation of classification of patient selection for reconstructive surgery, is rarely necessary before the age of five as it will not influence management. It may

help establish a diagnosis in some syndromic cases and is essential if a child presents with any symptoms or signs suggestive of an underlying ear infection. Cases of meatal stenosis (less than 2 mm) should be scanned between five and ten years of age to exclude cholesteatoma (see under Cholesteatoma in atretic ears). In younger children, a HRCT scan can predict bone thickness at the preferred site of implantation.

Otological surveillance

The child should be kept under otological surveillance to exclude conductive deafness due to otitis media with effusion (OME), particularly in unilateral cases and treatment started as appropriate. Conservative treatment with or without amplification is our standard approach, but if there are signs of retraction or structural changes to the drum, ventilation may be necessary.

Acute otitis media is fortunately rare in atretic ears, but parents and health professionals looking after such children should initiate immediate referral to an otologist if an infection is suspected. Prompt antibiotic treatment usually aborts the infection before mastoiditis or a subdural abscess develop. Failure to improve or signs of intracranial complications necessitate exploration after a HRCT scan. The safest method is to use a transmastoid approach.

Cholesteatoma in atretic ears

Congenital aural stenosis as compared to congenital aural atresia, carries a much greater risk of cholesteatoma. Jahrsdoerfer and Cole⁶⁵ reviewed 600 cases of major congenital ear malformations. Fifty patients (54 ears) were found to have aural stenosis. No cholesteatoma were found in children under three years of age regardless of the stenosis size. No bony erosion or middle ear involvement was encountered in children under the age of 12, but in patients over the age of 20, 60 percent had destructive changes. The most significant finding was that in children of 12 years or older with a meatus narrower than 2 mm, 91 percent develop cholesteatoma. Surgery is therefore recommended for these cases between the age of 6 and 12 years before any irreversible damage occurs. Surgery is similar to that for atresia.

Surgical treatment

Reconstruction of an atretic ear is possibly one of the most complex forms of otological surgery. Establishing and maintaining a canal, removing the atretic plate, identifying and mobilizing the ossicular complex and establishing a stable vibratory and medialized tympanic membrane, which will provide hearing thresholds better

than 25 dB, is an elusive goal achieved only by the most talented and experienced otologists. While the surgery for autogenous reconstruction of the pinna has progressed in recent years, improved outcomes in reconstructive middle ear surgery have generally been achieved by refining the criteria for selection. Conversely, Tjellstrom's pioneering work,⁶⁶ which led to the widespread introduction of the BAHA in Europe and more recently in the USA, has revolutionized the treatment of congenital conductive hearing loss.

Patients with congenital atresia have a number of options, which must be presented honestly to the family. Information about the likely success, potential complications and any alternative devices must be given in an unbiased fashion. Although there are problems with the steel band BCHA, the Softband or hard band BAHA adapter provides very good hearing, albeit with reduced speech discrimination in background noise and the recognized aesthetic and pressure problems.

The surgery for a BAHA is now well established⁶⁶ (see Chapter 239b, Bone-anchored hearing aids) and has proved to be a simple, safe and highly effective procedure. There is still some debate about the most appropriate age for implantation. We prefer to have 3 mm of cortical bone and a co-operative child who understands how to look after the aid and abutment, but in unusual circumstances children as young as two have been successfully implanted. Bone in children is softer and the potential for subcutaneous tissue regeneration greater, but if performed as a two-stage procedure with meticulous attention to detail, good osseointegration and a stable percutaneous implant site can be achieved.⁶⁷

RECONSTRUCTIVE MIDDLE EAR SURGERY

Preoperative considerations

Even the most experienced surgeons have problems providing useful hearing improvement, except in mild/moderate cases if evaluated against the Glasgow Benefit Scale. Surgical complications include damage to the facial nerve, a low but ever present risk and the possibility of a high frequency sensory neural hearing loss from transmitted acoustic trauma and postoperatively there is a significant risk of lateralization of the reconstructed drum and restenosis of the canal or meatus which contribute to concerns about long-term stability of any hearing improvement. In contrast, the BAHA offers a technically simple solution with a high success rate (greater than 94 percent) and no risk to the facial nerve or cochlea. It is an electronically processed sound, but studies suggest it provides a high quality of auditory rehabilitation.⁶⁸ Both techniques require periodic supervision from an otologist.

In the UK, Scandinavian and other EU countries, the BAHA has gained wide acceptance in the treatment of

complex conductive hearing losses caused by chronic suppurative otitis media (CSOM), stenosing otitis externa and complicated otosclerosis and is the preferred method of treatment for congenital aural atresia.⁴⁴ The commonly cited reason for avoiding a BAHA in patients with microtia and atresia (that it might adversely affect microtia repair) can be avoided by placing the implant site more posteriorly, away from any area of skin used in auricular reconstruction (Figure 75.22).⁶⁹

There are still patients who either need or could benefit from reconstructive middle ear surgery, particularly with grade I or grade IIa atresia or those patients with canal stenosis at risk of developing a cholesteatoma⁷⁰ and each case needs to be carefully assessed.

Despite the fact that BAHA implants have transformed the treatment of children with atresia, reconstructive surgery should still have a place in the surgical armamentarium of any unit treating such children. Jahsdoerfer has been responsible for much of the work over the last 25 years on correcting atresia and his contribution stems partly from his pursuit of surgical excellence and in part due to careful analysis of factors in patient selection that directly influence outcomes. His grading system (Table 75.4) is widely accepted as definitive for selecting patients for this type of surgery. In his hands, 80 percent of patients who score 8 or more will have thresholds better than 20 dB over 1, 2 and 4 kHz. A score of 7 indicates that approximately 70 percent of patients will achieve the same results.⁷¹

In Schucknecht's series⁴⁹ of 69 patients with varying degrees of atresia, only 30 percent of his patients who underwent canaloplasty and ossicular replacement had postoperative hearing better than 20 dB. De la Cruz *et al.*⁷² reported short-term success in closing the air-bone gap to less than 30 dB hearing loss (HL) in 58 percent of 116 cases undergoing atresia surgery, but this dropped to 50 percent with long-term follow-up. All these cases were categorized as moderate/severe atresia.

Important complications that might influence the decision to proceed with reconstruction are damage to the facial nerve, sensory neural hearing loss, restenosis of the canal and meatus, chronic infection and the stability of the improved hearing over time.

The course of the facial nerve can be reasonably accurately predicted by careful analysis of the stage of embryological arrest (see below under Embryology). HRCT may confirm these clinical impressions, but active facial monitoring and meticulous surgical technique are essential if damage is to be avoided. The danger areas are the acutely angled second genu, with the nerve passing anterolaterally in the lower portion of the atretic plate or even in the fibrous tissue lateral to a poorly formed plate (Cremers type IIb) with passage of the nerve through the glenoid fossa, rather than the stylomastoid foramen. It is also at risk when exiting from the lateral aspect of a micromastoid in patients with a low set microtia and, in some cases, the superficial portion of the facial nerve

© Hodder Arnold / Scott-Brown 7E

Figure 75.22 (a) The abutment for a bone-anchored hearing aid in a patient with bilateral microtia; (b) It is very important to insert the abutments posterior enough to allow ear reconstruction.

courses anterior to the tragus placing it at risk from soft tissue work over the anterior meatus and damage can occur even with flap elevation in autogenous or implant reconstruction. The reported incidence of temporary facial nerve palsy is 9 percent and of permanent weakness, 1.5 percent, all from extremely experienced surgeons.^{49, 73}

A high frequency sensorineural hearing loss caused by acoustic trauma occurs in up to 12 percent of cases.

Lateralization of the tympanic membrane (TM) from a foreshortened malleus handle or ossicular monoblock occurs in 9–15 percent, canal stenosis due to bony regrowth in 12 percent and soft tissue meatal stenosis in a further 10 percent. There is a significant rate of persistent or intermittent discharge from the neomeatus, particularly if a hearing aid is still required.

The anterior approach

This is the **most popular** of the three main surgical approaches, popularized by Jahrsdoerfer,⁹ de la Cruz⁷² and Lambert.⁵ Surgery is performed after microtia repair, via a post-auricular incision. Care is taken to avoid exposure of the autogenous cartilage of the reconstructed pinna. A temporalis fascia graft (TFG) is harvested and the periosteum incised at the posterior margin of the temporomandibular fossa and horizontally along the inferior margin of the temporal line. The posterior aspect of the glenoid fossa is identified, but deep dissection should be avoided as the facial nerve can occasionally exit the temporal bone into the TMJ. The tegmen tympani and glenoid fossa form the superior and anterior limits of dissection. If a remnant tympanic bone can be identified, drilling starts at this site, as it will lead to the atretic plate and middle ear (ME). If not, drilling starts over the cribriform area and the atretic plate is usually found at a depth of 1.5 cm. By drilling anterosuperiorly along the tegmen towards the epitympanum, the surgeon remains in a safe area away from the facial nerve. The mastoid is not opened as this creates a larger cavity with all the attendant postoperative problems. The dense atretic plate is 'egg shelled' with diamond burrs and partly removed with curettes. The fused incus and malleus may be seen superiorly on entering the middle ear cleft and produce the 'buttock sign', with a similar configuration to that noted at breach presentation. The atretic plate is commonly fused to the neck of the malleus whose handle may be absent and this is not disturbed until the ear canal has been widened, centred on the ossicular mass. The constraints of the new canal are the TMJ, middle cranial fossa, mastoid air cells and, inferiorly, the facial nerve. Finally, the bony attachment to the ossicular chain is removed by a slowly rotating burr or laser to minimize the risk of sensorineural hearing loss.

The mobility and continuity of the ossicles must be carefully assessed. Ideally, the chain will be mobile but if fixed or not in contact with the stapes the monoblock should be removed and replaced with a sculptured bony columellar or partial ossicular replacement prosthesis (PORP). Fixation of the stapes foot plate is fortunately rare and a contraindication to further surgery. The TFG is placed laterally, draped over the ossicular mass/columellar and extending 2–3 mm into the bony meatus. A 0.01-inch thick split skin graft measuring 5 × 7 cm is taken from the medial aspect of the upper arm, preferably with a

mechanical dermatome. After careful measurement, it is cut to form the exact lining of the new ear canal. If there is a thinner edge, it is placed medially with four notches but to create flaps which will cover the fascial graft. A silastic disc is placed over the new TM and the canal filled with a Meroce[®] ear wick hydrated with antibiotic and steroid eardrops. The lateral graft is folded over the wick, while the new meatus is created.

The reconstructed ear may not be in the correct anatomical position for the meatus. Generally it needs to be elevated in a posterosuperior direction. This is achieved by freeing the ear anteriorly and excising an ellipse of skin from the superior aspect of the post-auricular incision. With the ear held in this new position the meatus is marked and an oval of skin and cartilage removed. If conchal cartilage is present, less contraction occurs and a diameter of 1.5 times normal will suffice. The cartilage framework is sutured into its new position with 3/0 Vicryl and the skin graft stitched to the meatal skin with 5/0 Vicryl Rapide. A further Meroce wick is inserted and hydrated and the lateral aspect covered with Bactroban[®] ointment. The post-aural wound is closed and a mastoid pressure dressing applied.

All of the packs and post-auricular sutures are removed at one week and the new ear canal is filled with antibiotic steroid drops, which are removed with microsuction after five minutes. The drops are used at home for a further week and the patient is seen two weeks later when the desquamated layer of the skin graft can be removed and the new canal and TM inspected. Granulation tissues are treated with silver nitrate cautery and most resolve with careful microsuction and Triadcortyl[®] ointment, but it can take several weeks for the ear to stabilize.

Transmastoid approach

This employs a more posterior route to the middle ear cleft using the dura of the middle cranial fossa, the sigmoid sinus and sinodural angles as landmarks to the antrum with subsequent identification of the lateral semicircular canal (LSCC), atretic plate and, if possible, the facial nerve. The atretic plate is removed in a similar fashion, trying to centre the cavity on the stapes. The aim is to create a stable, small, cavity lined with squamous epithelium. A split skin graft (SSG) of 0.01 inch is used to line the cavity after a temporalis fascia tympanoplasty. Obliteration of the cavity with soft tissue flaps and bone p  te have had mixed results.⁷⁴ The soft surgery and postoperative management are similar to the anterior approach.

Modified approach

In patients with thick non-pneumatized atretic plates, a modified anterior approach has been proposed.⁷⁵ The sinodural angle is opened with limited dissection

anteriorly to expose the posterior antrum identifying the lateral semicircular canal and ossicular mass. An anterior approach can then be performed with much more certainty. Image-guided surgery may provide a similar degree of reassurance.

Complications

The major operative concerns for the patient and surgeon are potential damage to the facial nerve and the risk of sensorineural hearing loss from transmitted energy from the drill. Three-dimensional HRCT scanning helps provide an accurate spacial template for the surgeon and image-guided surgery is becoming simpler to configure and more accurate. Some systems, such as BrainLAB (Cambridge, UK), offer accuracy to within 1 mm and as these systems come online they may become as indispensable as active facial nerve monitoring.

There has been considerable debate about the hearing results and long-term stability of atresia surgery. Unless the hearing is better than 25 dB HL, a patient is likely to require a hearing aid which increases the incidence of infection in the neomeatus and begs the question – why not use a BAHA which has none of the attendant risks and a very high success rate both in terms of osseointegration, implant site stability and patient satisfaction? In unilateral cases, the arguments in favour of nonintervention, at least until the patient is old enough to sign their own consent form is even greater. The Glasgow Benefit Scale merely confirms what many otologists have known for years that unless the hearing is within 20 dB of the normal ear, the patient is unlikely to perceive any benefit. Realistically, this limits selection for surgical reconstruction to types I and Ia, with a score of 8+ on the Jahrsdoerfer scale. The long-term stability of hearing improvement has been questioned. Lambert⁵ reported a series of 55 patients on whom an initial speech reception threshold of less than 25 dB was achieved in 60 percent of patients in the early postoperative period, but in the longer term (mean 2.8 years) this was maintained in only 46 percent of patients and revision surgery was necessary in one-third of those patients. Chandrasekhar *et al.*⁷⁵ reported closure of the air-bone gap to less than 30 dB in 60 percent of patients with a mean follow-up time of 2.6 years and in only 54 percent in cases of revision surgery.

Lateralization of the TM and ear canal stenosis is common. Schucknecht⁴⁹ reported that 26 percent of 69 ears developed stenosis requiring revision surgery and Jahrsdoerfer and Hall⁷⁶ found that 50 percent of patients with grade III microtia developed the same complication. Chandrasekhar *et al.*⁷⁵ found that 22 percent of his cases developed restenosis and 9 percent developed lateralization of the TM. Linstrom *et al.*⁷⁷ found some degree of postoperative blunting and cicatrization of the neomeatus in 75 percent of children in his series of 69 ears.

THE BONE-ANCHORED HEARING AID

Patient selection and age at implantation

Even in the very best hands the success rates for aural atresia surgery are less than ideal, both in terms of hearing improvement, restenosis and long-term stability. With very careful selection, more predictable results can be obtained, but in the majority of cases the BAHA offers a low risk, highly acceptable and predictable method of auditory rehabilitation.

Many factors influence the age of implantation. After the age of five, there is usually sufficient bone and a co-operative child. In cases where it is difficult to use a bone conduction hearing aid or BAHA® Softband, for example, craniosynostosis, implants have been successfully inserted at two years of age. Use in adults has been widely reported and a study on 100 children under the age of 16 years⁵⁹ confirmed that 95 percent achieved a successful percutaneous implant over an average eight-year period. Skin reactions were noted in 9 percent of patients over a 21-year follow-up period, soft tissue regeneration and appositional bone growth are recognized problems and revision surgery in some form is required in 22 percent of children.⁵⁹ Parents and children need to have realistic expectations, helped by the introduction of the trial headband for the BAHA. Family support and commitment to cleaning the skin around the abutment is vital.

Otological and audiological criteria

Patients with congenital atresia are good candidates for implantation, particularly if they have good cochlea function and are not suitable for reconstructive surgery of the ear canal and middle ear. Patients who have had an unsuccessful reconstruction or particularly if the ear discharges with the air conduction hearing aid are suitable, as are patients with unilateral atresia if they find the 'blind area' a handicap.

Average bone conduction thresholds (0.5–4 kHz) should be better than 45 dB for the Baha Divino™, better than 55 dB for the Baha Intenso™, or up to 60 dB average for the more powerful body-worn Baha® Cordelle II aid. Speech discrimination should be better than 60 percent, but in the rare case of a congenital atresia with sensorineural loss, implantation may be the only way of introducing sound to the cochlea. Directional microphones and radio-aid links are available.

Surgery for BAHA

The technique for implantation is discussed in Chapter 239b, Bone-anchored hearing aids and the BAHA operating theatre manual produced by Entific Medical Systems

(now part of Cochlear) is available online at www.cochlearamericas.com/Professional/login.asp. We use a two-stage procedure in children under 12 years to protect the site of osseointegration, but would use single-stage surgery if 4 mm of bone were present. The local skin graft is thinned to 0.2–0.5 mm to remove all the hair follicles. Particular attention is given to subcutaneous tissue reduction, as the potential for regeneration is greater in children and the most common cause for skin reactions. A 4-mm flange fixture is used whenever possible. The bone tends to be softer in children and only gentle pressure is needed on the countersink drill and the torque settings are kept low (20–30 Ncm). If the bone is thin, the flange is left 1 mm proud of the surface and the space augmented with bone dust under a periosteal flap or an expanded polytetrafluoroethylene membrane.⁶⁶ In both cases, the interval between the stages is extended to six months. The site of implantation and subcutaneous tissue reduction must be kept away from any skin that might be needed for autogenous reconstruction of the pinna.⁷⁸ The BAHA should be 65 mm behind the site of the anticipated external auditory meatus which is often further posterior than expected to take into account any possible future ear reconstruction (Figure 75.22).⁶⁹

Parents must be taught how to clean the percutaneous site to minimize the risk of infection. Skin reactions are slightly more common in children during the first year, but are managed by cleaning with Bactroban ointment or occasionally the use of an anti-staphylococcal antibiotic. Thereafter, rates of inflammation at the percutaneous site are similar to adults. Eighteen percent of our children have required revision surgery, mainly for soft tissue reduction, but increasingly for appositional bone growth, which buries the fixture. An elongated snap coupling (8.5 mm) is available, but removal of bone or reimplantation is occasionally needed. Loss of the implant over a prolonged period of 15 years has occurred in 6 percent of our children, consistent with reports from other centres.⁶⁶

Audiological evaluation of BAHA

BAHA provide a reliable and predictable adjunct for auditory rehabilitation in patients with a conductive or mixed hearing loss who are unable to benefit from conventional hearing aids.⁷⁹ Many studies report that audiometric benefit from the BAHA is greater than from conventional bone conduction hearing aids both with regard to warble tone thresholds and speech discrimination in a noisy environment.⁸⁰ It is suggested that patients with congenital atresia achieve marginally the best freefield thresholds and speech discrimination compared to other BAHA cases.⁴⁴ Improved sound quality, appearance and practicality were also noted. Ninety percent of more than 300 patients in the Birmingham study used their implants for more than eight hours every day.⁸¹

In a study of 19 children implanted with a BAHA for congenital aural atresia, Powell found all of the children who had previously used air conduction aids achieved better freefield warble tones and 71 percent had improved speech discrimination. Of the children who had used conventional conductive hearing aids, 50 percent were found to have improved speech discrimination with the BAHA. Most of the children felt the BAHA was more effective in a noisy environment.⁸² Bosman *et al.*⁸³ evaluated the audiometric results of fitting bilateral BAHAs in 25 patients (with congenital bilateral atresia) and found improved speech reception thresholds in quiet environments and with noise, symmetrical localization resulting in binaural hearing. These results are supported by the Birmingham group.⁸⁴ Wazen *et al.*⁸⁵ studied the effect of fitting a BAHA in unilateral conductive and mixed losses and found significant improvement in the hearing handicap score with the BAHA.

Complications

Inadvertent penetration of the lateral venous sinus due to thin bone can occur. The implant seals the hole. Skin reactions are not uncommon in the first year and loss of the fixture due to late failure of osseointegration or direct trauma occurs in 6 percent of cases. The practice of fitting a 'sleeper' fixture at the time of the first operation remains open to debate. In cases of resistant percutaneous inflammation, the abutment can be removed and reattached when the skin has healed. If this fails, revision subcutaneous tissue reduction is probably needed.

KEY POINTS

- Minor congenital anomalies of the ear are common.
- Major congenital anomalies of the outer or middle ear demand coordinated care from a highly skilled multidisciplinary team able to offer the full spectrum of otological, cosmetic and psychological support.
- One of the main functions of the team is to act as an information centre so that the family understand all of the options and have an appreciation of the timescale involved.
- The major options for microtia are autogenous reconstruction and an implant-retained prosthesis with the very definite third option of doing nothing.
- Good results with autogenous reconstruction are only available in a few centres.
- The authors regard autogenous reconstruction as the treatment of first choice for microtia, reserving implant surgery for

children who make a very conscious decision not to have reconstruction or for those referred following unsatisfactory plastic surgery.

- Despite the fact that BAHA implants have transformed the treatment of children with aural atresia, middle ear reconstructive surgery should still have a place in the surgical armamentarium of any unit treating such children.
- Reconstructive surgery for atresia is some of the most demanding surgery in otology.

Best clinical practice

- ✓ Flexible wire splints (Ear Buddies) totally encased in silicone are now commercially available for parents themselves to apply to their child's ears. For prominence, rim kinks, Stahl's bar and other abnormal folds, the splints used carefully in infancy may avoid the need for later surgery. [Grade C/D]
- ✓ Surgeons who engage in the correction of 'bat ears' need to be adequately trained for this work and should audit their results. [Grade D]
- ✓ Autogenous reconstruction for microtia is best delayed until the child is ten years old. [Grade C]
- ✓ All children with atresia have problems localizing sound and we emphasize how important it is to instil the practice of stopping and looking carefully in both directions before crossing roads, as there is an increased risk of road traffic accidents in these children. [Grade C]
- ✓ Microtia and atresia should automatically place the child on a high-risk register for sensorineural hearing loss even if unilateral. [Grade A]
- ✓ Patients with syndromes involving craniofacial malformations, including Treacher Collins, Goldenhar syndrome, Crouzons and Pierre Robin sequence are considered poor surgical candidates for atresia repair. [Grade C/D]
- ✓ Cases of meatal stenosis (less than 2 mm) should be scanned between five and ten years of age to exclude cholesteatoma. [Grade C/D]
- ✓ In unilateral atresia, unless the hearing is within 20 dB of the normal ear, the patient is unlikely to perceive any benefit from reconstructive surgery. Realistically, this limits selection for surgical reconstruction to types I and Ia, with a score of 8+ on the Jahrsdoerfer scale. [Grade C/D]
- ✓ With very careful selection, more predictable results can be obtained in reconstructive middle ear surgery, but in the majority of cases the BAHA offers a low risk, highly acceptable and predictable method of auditory rehabilitation. [Grade B]

Deficiencies in current knowledge and areas for future research

- 'Splints' applied by parents are assuming an ever more important role in the management of minor cartilaginous deformities.
- The establishment of specialist centres for BAHA and for the management of congenital ear deformity is enabling more focused, controlled trials and better comparison of results.
- The technology that underpins osseointegration is improving rapidly. As experience with these techniques develops more reliable results and lower complication rates are possible.

Sound and speech production and disorders	992		

SEARCH STRATEGY

The references for this chapter were compiled from a Medline search using the terms 'speech and language disorders' and 'child'. The Cochrane database was also consulted.

INTRODUCTION

Communication is a fundamental part of the development and maturation of the child. Otolaryngologists are often directly involved in the investigation and management of disorders of communication, be they receptive disorders such as hearing loss, or expressive disorders, for example dysphonia and dysarthria.¹ Speech and language therapists (SLT) have particular expertise in the assessment and treatment of children with such disorders and optimum care of these children is brought about by close cooperation between SLTs, otorhinolaryngology (ORL) paediatricians and other health care professionals.

Speech and language therapists are independent professionals with a large body of scientific knowledge, diagnostic and therapeutic skills. In a short chapter such as this, it is possible only to make ORL clinicians aware of the commoner clinical presentations and to highlight the main principles that underpin SLT as it applies to children who may attend an ORL clinic.

NORMAL DEVELOPMENT OF SPEECH AND LANGUAGE

The development of speech and language starts at birth. Sensory stimulation is essential. Children learn by imitation, experimentation and feedback. Although there is considerable variation, progress is through a series of defined stages.² Some of the key stages are shown in **Figure 76.1**. In the first few weeks, some degree of differentiation of cry, for example 'hunger' and 'pain', becomes apparent. The **phonation stage** describes the period in the first two to three months of life when the infant produces predominantly vowel-like sounds, commonly known as 'cooing'. The infant then begins to articulate sounds while vocalizing. This **primitive articulation stage** is frequently referred to as 'gooing'. The normally developing infant continues to produce a wider repertoire of sounds and in the **expansion phase** begins to combine vowels and consonants. The process for the infant culminates in the **canonical babbling phase** with

Figure 76.1 Stages in the development of speech and language.

● Hodder Arnold / Scott-Brown 7E

the infant producing strings of syllable-like sounds, for example 'baba', 'mama' or 'dada'. This phase typically begins to emerge at around six months of age. Multiple studies report that normally developing babies rarely begin canonical babbling later than ten months of age.^{3,4,5,6} Thus the absence of the canonical babbling phase at this age has been proposed as an early indication of developmental speech and language problems.

Vocabulary, verbal and linguistic skills develop rapidly in the next two years. Throughout the second year of life normally developing children acquire an increasing vocabulary of single words. By two years, most infants will use at least 50 single words and will be beginning to produce two-word phrases. However, language development is not restricted to the knowledge and use of an increasing number of words.

Receptive language skills emerge as the child begins to understand simple instructions accompanied by gestures, for example 'give it to me', and progresses through following simple instructions in a familiar, predictable situation, for example 'wave bye-bye' while walking away. By two years of age typically developing children can identify familiar items from a small range without gestures or other cues. Receptive language skills develop prior to expressive skills.

A child who has no words by 20–24 months, no phrases at 28 months or who is not speaking intelligibly at three years is a cause for concern and should be investigated. It is axiomatic that parental concern about a child's development should always be acknowledged and

warrants investigation. While parental concern may be a lack of expressive language, potential deficits in comprehension should also be explored.

CLASSIFICATION AND PRESENTATION OF DISORDERS

There are several systems for the classification of speech and language disorders but for practical purposes it is useful to consider **receptive**, **expressive** and **mixed** disorders (Table 76.1).⁷ Children in whom the pattern of speech and language development is atypical and who do not appear to have other developmental disorders are often referred to as having a **specific language impairment** (SLI), although this distinction is not always clear and its validity as a precise diagnostic label has been questioned.⁸ Clinical presentations range from complete inability to speak in children with severe developmental disorders to minor errors of fluency or pronunciation. In practice, otolaryngologists are asked to deal with children in one of two categories, i.e. those who are 'slow to speak' (speech or language delay) or those in whom there is concern regarding pronunciation or intelligibility (sound and speech production disorders or disorders of articulation or fluency).

Delay in either speech or language is reported in 6 percent of otherwise healthy preschool children.⁹ The proportion is much higher in children with global developmental delay, cerebral palsy or neurological

Table 76.1 Classification of speech and language disorders in children.

Receptive disorders	Expressive disorders ^a	Combined disorders
Neurological: secondary to cognitive impairment (language comprehension)	Voice disorders	Psychological morbidity, e.g. autism, ADHD
Sensory: secondary to hearing or visual impairment	Oropharyngeal structural disorders, e.g. cleft palate, rhinolalia	Developmental disorders, e.g. cerebral palsy
Environmental: poor sensory stimulation	Motor nerve and cortical disorders, e.g. dysarthria	
	Fluency disorders (stuttering)	

^aSound and speech production.

disorders, in children on the autistic spectrum, and in children with attention deficit hyperactivity disorder (ADHD).¹⁰ Co-morbidity is common and it is important for clinicians to have a high index of suspicion as the presentation of any one of the above conditions may be with a speech and language disorder. Screening programmes and vigilance among primary care health workers in western countries have ensured that congenital deafness is usually diagnosed before the child develops speech. In developing countries, speech delay is still an important mode of presentation of congenital deafness.

SPEECH AND LANGUAGE DELAY

Delay in speech and language development is the most common developmental disorder affecting children between 3 and 16 years.⁷ Children who are slower than their peers to speak cause significant anxiety to their parents and other caregivers. Although delayed speech is ‘a delay in speech and/or language development compared with controls matched for age, sex, cultural background and intelligence’,⁷ there is no universal definition of ‘late talkers’ that focuses on particular developmental milestones. Using the criteria of Rescorla,¹¹ children who at 24 months use fewer than 50 single words and/or use no two-word combinations, the prevalence of ‘late talking’ is between 10 and 15 percent of the population. Law *et al.*⁹ in a Cochrane review quote a prevalence rate of 6 percent.

While some late talkers spontaneously improve, more than half of children who are late to talk have continuing language delay at three years and those who have little or no speech at 30 months are at increased risk of persistent problems. Children with persisting difficulties are at risk of ongoing problems with literacy, behaviour, socialization and educational performance. Rescorla¹¹ reports persistent weaknesses in language-related skills in a group of adolescents who were identified as late talkers between 24 and 30 months. Brownlie *et al.*¹² report adolescents with a history of language impairment had higher rates of arrests and convictions than those with isolated speech impairment or their normally developing peers. Risk factors for poorer outcomes for late talkers include hearing impairment, a positive family history of speech

and/or language delay and mixed (receptive and expressive) delay.

Most children with delayed speech have primary speech and language delay but in almost 50 percent the speech and language disorder is part of a global pattern of developmental delay. In children with global delay the prognosis is less good and dependent on the natural history of the underlying condition.⁹

It is essential to take a thorough history including details of the pregnancy and delivery, developmental milestones and the child’s feeding history. A full clinical developmental assessment including age-appropriate testing of cognitive function may be needed. The otolaryngologist must arrange for age-appropriate assessment of the child’s hearing and check the status of the middle ears, as otitis media may be a factor in reducing sensory input.

The challenge is to identify those children whose problems will not spontaneously resolve and to identify appropriate interventions for them.

In a systematic review of the effectiveness of speech and language interventions for children with primary speech and language delay/disorder, the authors report that overall there is a positive effect of SLT interventions with best results for children with expressive disorders. The effect of intervention for children with receptive disorders is less predictable.⁹ [****]

SOUND AND SPEECH PRODUCTION AND DISORDERS

Normal speech production

Speech production is dependent on three components: respiration, phonation and articulation. Respiration is the current of air from the lungs, which forms the medium for the production of sound. This is modified by the vibration of the vocal folds (**phonation**) to produce ‘voice’ and then by alteration of the size, shape and position of the structures in the mouth and pharynx notably the tongue, lips and palate (**articulation**). Subtle changes in the quality or ‘timbre’ of the spoken word

(**resonance**) are also brought about by the air-containing cavities of the pharynx, the nose and the paranasal sinuses.

The velopharyngeal sphincter is important in the production of speech. The sphincter marks the junction between the nasopharynx and the oropharynx and closes during swallowing to prevent reflux of food and fluids into the nasal cavity. It is open during nasal inspiration and closes for the most part during speech except for the sounds 'm', 'n' and 'ng'. Disorders of voice where the pathology is in the larynx are dealt with in Chapter 90, Paediatric voice disorders.

Disorders of articulation

Articulation disorders may be idiopathic but neurological dysfunction, developmental delay, lack of coordination of movements in the mouth or pharynx, dental anomalies, malocclusion, or tongue problems, such as microglossia and macroglossia, must be considered. A thorough otolaryngological assessment will include age-appropriate assessment of hearing and examination of all of the structures of the head and neck involved in the production of speech.

Nasal speech (rhinolalia)

Otolaryngologists may be asked to see children with abnormalities of pronunciation described as 'nasal' speech. Excessive nasal air escape during speech gives rise to **hypernasal speech** or **rhinolalia aperta**. In **rhinolalia clausa** the normal pattern of nasal escape when speaking 'nasal' sounds, for example nn, mm and ng, is obstructed. There may be a mixed hypo- and hypernasal pattern.

The distinction between these varieties of nasal speech can be difficult for the untrained ear; hence thorough assessment by a speech and language therapist is essential before commencing treatment.

HYPERNASAL SPEECH

In hypernasal speech (rhinolalia aperta) the velopharyngeal sphincter remains open or partly open during speech and air escapes into the nasal cavity. Causes include palatal paralysis, for example diphtheria, cerebral palsy, cleft palate, submucous cleft, adenoidectomy, and craniofacial surgery such as midfacial osteotomy. Placing a cold steel spatula under the nostrils and observing the misting pattern as the child speaks is a useful clinical test for the condition. Some nasal escape is normal during 'nasal' sounds such as mm, nn and ng, but misting when the child speaks a phrase with no nasal sounds, for example 'Katie's sister was six yesterday', is suggestive of

palatal dysfunction. In established cases, there may be compensatory nasal grimacing as the child attempts to correct the nasal escape. Velopharyngeal insufficiency and submucous palatal clefts are dealt with in Chapter 77, Cleft lip and palate.

HYPONASAL SPEECH

Hyponasal speech (rhinolalia clausa) can be caused by septal deviation, polyps, gross turbinate hypertrophy, adenoids or a space-occupying nasopharyngeal lesion. The spatula test shows no escape when the child is asked to speak words with 'nasal' sounds, for example 'Mummy and nanny are mending' will be pronounced 'Bubby and daddy are bedding'.

Tonsils, adenoids and speech

Tonsillectomy may affect the 'timbre' or resonance of the singing voice and in the case of children who sing it is wise to inform them and their parents of this. Adenoidectomy causes transient velopharyngeal sphincter dysfunction in about 5 percent of cases. This can cause troublesome rhinolalia aperta. In a small minority (0.01 percent) this may be longstanding.^{13, 14}

Children with submucous palatal clefting – where the only external sign may be a bifid uvula – should have adenoidectomy with extreme caution if at all. Partial adenoidectomy, under direct or endoscopic vision and preserving a buttress of tissue around the lateral margins may preserve the velopharyngeal closure mechanism.¹⁵

Hyponasal speech due to large adenoids rarely constitutes an indication for adenoidectomy on its own. Usually there will be an independent indication for surgery, for example airway obstruction. Adenoids regress and parents should be made aware of this when giving informed consent if adenoidectomy is offered to improve the child's speech.

Fluency disorders (stuttering)

'Fluency' refers to the organization, structure and sequence of speech patterns. Some degree of dysfluency is developmental but persistent stuttering – characterized by abnormal prolongations interruptions and syllable repetitions – can cause significant difficulties which persist into adult life.

Stuttering typically starts in the third and fourth years of life, typically in children whose speech and language development is otherwise normal. The aetiology is unknown, but there is a familial association and boys are more commonly affected than girls. There is no association with tongue tie or with adenotonsillar

disorders and no evidence to justify surgery of any sort for stuttering.

The available evidence supports early intervention – in the preschool years – under the supervision of a speech and language therapist.¹⁶ [****]

Tongue tie

Tongue tie (ankyloglossia) is characterized by tethering of the anterior part of the tongue to the floor of the mouth by a short lingual frenulum. It is usually asymptomatic but may restrict tongue mobility in the newborn and give rise to difficulties with breastfeeding. Many parents present for treatment as they are concerned about the appearance of the tongue or about the potential for the condition to interfere with activities such as licking the lips and kissing. The condition tends to improve as the child gets older.¹⁷

There is no evidence to link tongue tie with speech and language disorders. Nevertheless, parents often request treatment. If treatment is required, a simple division of the frenulum is adequate. In the newborn, this can be undertaken without anaesthesia but older children require a general anaesthetic.

KEY POINTS

- Speech and language disorders – particularly delayed speech – are common in children.
- In very young children most cases of speech and language delay resolve spontaneously.
- Persistent speech and language difficulties in young children are predictive of long-term problems affecting behaviour, learning and school achievement.
- Adequate stimulation is essential for normal development of speech and language.
- Deafness may be a key factor in the aetiology of speech and language disorders. Delayed speech is still a common mode of presentation of deafness.

Best clinical practice

- ✓ Normally developing babies rarely begin 'canonical babbling' later than ten months of age. Absence of the canonical babbling phase at this age is an early indication of developmental speech and language problems. [Grade B]
- ✓ A child who has no words by 20–24 months, no phrases at 28 months or who is not speaking

intelligibly at three years is a cause for concern and should be investigated. [Grade B/C]

- ✓ Global developmental delay, cerebral palsy, neurological disorders, children on the autistic spectrum and children with ADHD may present with a speech and language disorder. [Grade B]
- ✓ The distinction between the different varieties of nasal speech (rhinolalia) can be difficult for the untrained ear; hence thorough assessment by a speech and language therapist is essential before commencing treatment. [Grade C/D]
- ✓ Stuttering is best managed by early intervention – in the preschool years – under the supervision of a speech and language therapist. [Grade A]
- ✓ There is no good evidence of an association between tongue tie and disorders of speech and language. [Grade A]

Deficiencies in current knowledge and areas for future research

- The evidence base that underpins current practice in speech and language therapy is improving steadily. Many treatments are now the subject of randomized controlled trials and systematic reviews.
- Developmental paediatrics is a well-established subspecialty. Children with developmental disorders often have speech and language disorders and are increasingly being seen in multidisciplinary clinics where access to speech and language therapy is improving.

INTRODUCTION

Clefts of the lip and palate are the among the most common congenital birth anomalies. The reported incidence varies between 0.4/1000 and 3.7/1000 live births.¹ The condition usually presents as an isolated anomaly (nonsyndromic cleft lip and/or palate) but may be associated with other congenital defects (syndromic cleft lip and/or palate). This chapter describes the epidemiology, embryogenesis and aetiology of cleft lip and palate and then focusses on the principles of treatment.

CLASSIFICATION

Many different classification systems of varying complexity have been proposed for cleft lip and palate. The simple ones are easy to use, but fail to distinguish between phenotypic characteristics that may be significant with regard to aetiology and treatment outcome.

Veau's 1931 classification, which has four categories, is an example of a simple system.² It is incomplete since it makes no provision for isolated cleft lip or alveolus. The earliest symbolic representation appears to have been developed by Pfeifer in 1966 (**Figure 77.1**).³ Kernahan and Stark's classification was developed and represented symbolically as a 'striped Y' by Kernahan in 1971 (**Figure 77.2**).⁴

Kriens introduced a simple coding system for paraphrasing cleft lip and palate in 1987.⁵ This system represents the anatomic site, and the side and type of cleft (complete, partial, microform) in a simple alphabetical code – LAHSHAL. Complete clefts are recorded in upper case, partial clefts in lower case and microform clefts are denoted by an asterisk (**Figure 77.3**). This system has been widely used and has the advantage of being easy to record in medical records and electronically.

Two systems of contrasting complexity in use today are the American Cleft Palate Association's detailed classification designed in 1962 and a much simpler variation of the symbolic 'Y' system currently used in the UK.

Figure 77.1 Pfeifer's symbolic classification.

Figure 77.2 Kernahan's striped 'Y' classification. 1, 4, lip; 2, 5, alveolus; 3, 6, hard palate anterior to incisive foramen; 7, 8, hard palate; 9, soft palate; 0, incisive foramen.

Figure 77.3 LAHSHAL - anatomic paraphrase of cleft lip, alveolus and palate. A, alveolus; H, hard palate; L, lip; S, soft palate.

True median clefts fall into a category outside the classification systems for clefts of the lip and palate described. They can occur as an isolated malformation or may occur with holoprosencephaly (failure of the prosencephalon to sufficiently divide into the double lobes of the cerebral hemispheres). The result is a single-lobed brain structure and severe skull and facial defects.⁶

Tessier⁷ described an anatomical system of classification for craniofacial clefts, which depended on the site and the relationship of the cleft to the midline sagittal plane. The classification describes 14 different types of clefts according to whether they are cranial or facial and their relation to the midsagittal line. The system facilitates description of both the site and severity of clefting. Clefts of the lip and alveolus are numbered 1, 2 and 3. The causes of most clefts are unknown; some are malformations and some represent disruptions caused for example, by amniotic bands. The vast majority are sporadic with a few exceptions including the autosomal dominant inherited Treacher Collins syndrome.

EPIDEMIOLOGY

There are racial differences in incidence with the highest incidence of cleft lip and palate reported in Native Americans (3.7/1000 live births) and the lowest in children of Afro-Caribbean descent (0.3/1000 births).¹ In Europe, there appears to be a clear difference between north and south with the lowest rate of 6.3 per 10,000 in El Valles, Spain and the highest (2.62/1000) in Finland.⁸ [**]

Cleft lip with or without cleft palate (CL/P) is more common in boys. The more severe the defect, the greater the proportion of males affected. The male:female ratio is 2:1 for cleft lip and palate reducing to 1.5:1 for isolated cleft lip (CL). This contrasts with the incidence of isolated cleft palate (cleft palate only, CPO) which is lower at around 0.62/1000, shows less variation in different racial groups and is more common in girls (sex ratio = 0.83).⁸ Associated malformations occur more frequently in infants who have CPO than in those with CL/P.^{9, 10, 11, 12} [**]

Clefts of the lip may be incomplete or complete, unilateral or bilateral. Unilateral cleft lip occurs twice as commonly on the left side. Approximately 10–30 percent are associated with skin bridges that connect the medial and lateral cleft elements known as Simonart's bands. Cleft palate (CP) may involve just the soft palate or extend into the hard palate. Submucous cleft of the soft palate where the mucosa is intact but the underlying tissues are 'cleft' has been reported in approximately 1 in 1200 to 1 in 2000 births,⁹ similar to the incidence of overt CPO. [**]

There is evidence from epidemiological studies that infants with cleft lip and palate have an increased risk of mortality in the first years of life.¹³ This increased mortality is greater than that accounted for by the presence of other associated anomalies. [**]

NORMAL EMBRYOGENESIS

In the embryo, the face appears to develop at the end of the fourth week and is complete by the eighth week of pregnancy. The palate is completely formed by the end of the tenth week. The process of facial development starts with the migration of neural crest cells into the facial region to form the facial mesenchyme. This migration starts just before the neural folds fuse to form the neural tube at the end of the third week.

A series of swellings appear around the stomodeum at the end of the fourth week (Figure 77.4). These correspond to the frontonasal process, the bilateral maxillary process and the mandibular process. The developing nasal placodes arise as thickenings on either side of the frontonasal process. During the fifth week, the nasal placode becomes surrounded by a horseshoe-shaped ridge consisting of lateral and medial nasal processes creating a nasal pit in the middle. The nasal pits continue to deepen and eventually rupture, forming communications between the nasal and oral cavities, called primary choanae.

By the seventh week, the maxillary processes have advanced medially underneath the lateral nasal swellings and fused with the medial nasal swellings which themselves have merged with each other. This complex comprising the fused medial nasal swellings and maxillary swellings forms the primary palate and is complete by the end of the seventh week (Figure 77.5).

During the sixth week, two shelf-like swellings project medially from the maxillary process behind the primary palate (Figure 77.6a). Their medial edges hang vertically downwards either side of the tongue surrounded by a layer of undifferentiated epithelial cells, two to three layers

Figure 77.4 Development and fate of the facial processes. Representation of a 30–32-day-old human embryo showing the development of the facial processes. FNP, frontonasal process; MAX, maxillary process; MAN, mandibular process; MNP, medial nasal process; LNP, lateral nasal process.

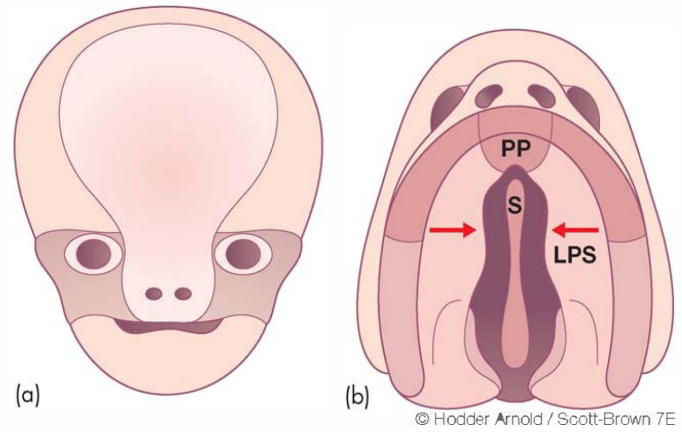

Figure 77.5 Representation of seven-week-old embryo showing the fate of the facial processes (a) frontal view; (b) ventral view of primary and secondary palate. LPS, lateral palatal shelf; PP, primary palate; S, nasal septum.

thick and referred to as medial edge epithelium (MEE). At a precise moment during the seventh week (about seven days later in female compared to male embryos), the drooping palatal shelves rapidly elevate during a matter of minutes or hours to a horizontal position (Figure 77.6b).^{14, 15} The shelves make contact in the midline and the opposing layers of MEE adhere to each other. The MEE disappears and mesenchyme flows across the palate. Fusion of the palatal shelves is complete by the tenth week. Although there is some controversy as to the fate of the MEE there is no doubt that its role in exposing underlying mesenchymal tissue is crucial to successful fusion of the palatal shelves.

Bone formation in the palatal processes of the maxillary and palatine bones is dependent on the differentiation of osteogenic blastomas from the mesenchyme of the hard palate. The muscles of the soft palate are formed by the migration of mesoderm from the pharyngeal wall.¹⁶ Formation of the nose is completed by the development of the secondary nasal septum from

mesenchyme which extends down from the roof of the primitive nasal cavity to fuse with the palatal shelves in the midline.

EMBRYOPATHY OF FACIAL CLEFTING

Facial clefts can occur as part of a syndrome or as isolated clefts. Nonsyndromic cleft lip with or without cleft palate is considered as aetiologically distinct from cleft palate only. Nonsyndromic cleft lip and palate is the result of an embryopathy culminating in a failure of fusion between maxillary mesenchymal processes. It is composed of two separate entities: cleft lip with or without cleft palate and cleft palate only. This distinction is supported by embryological considerations, as well as genetic studies.

Evidence on the aetiology of facial clefting is derived from a combination of epidemiological studies, animal model studies (mainly murine models) and human genetic and *in vitro* studies. A positive family history can be identified in 20 percent of patients in different populations, which supports the view that genetic factors have an important role in the aetiology of facial clefting. A picture has emerged which supports a genetic predisposition to disruption of the normal development and fusion of the mesenchymal processes resulting in malformations that are disclosed by environmental factors.

Essentially a cleft is caused by one or a combination of the following: hypoplasia, abnormal directional growth of mesenchymal processes, failure of fusion or breakdown of fusion of mesenchymal processes.

Failure of palatal shelf elevation may be responsible for 90 percent of palatal clefting.⁹ In some cases obstruction of palatal shelf elevation by the tongue secondary to micrognathia may be a contributory factor in palatal clefting as may occur in Pierre Robin sequence.

GENETIC FACTORS

The development of detailed structures of the head and face is mainly determined genetically.¹⁶ Nonsyndromic

clefting occurs in the absence of other physical problems or any evidence of delay in motor or cognitive development. Both nonsyndromic CPO and CL/P have a genetic background that is probably disclosed by environmental factors. About 70 percent of cases of CL/P and 50 percent of CPO are nonsyndromic.^{17, 18} Evidence that genetic factors play an important role in the aetiology of CPO and CL/P is forthcoming from population studies, most notably the study by Fogh-Anderson in 1942.¹⁹ A recent study that compared CL/P and CPO showed concordance values in CL/P for monozygotic twins and dizygotic twins of 40 percent and 4.2 percent compared with values in CPO of 35 and 7.8 percent, respectively.²⁰ [**]

Most of the genetic studies are based on segregation, allelic association and linkage analyses.^{21, 22} Proposed aetiologies include single gene causes, chromosomal disorders and polygenic interactions. The proposition of divergent models for orofacial clefting has implications for genetic counselling which continues to be informed by empirically derived risk data (Table 77.1).²³

Association and linkage analysis attempt to map a disease gene on a chromosome using genetic markers. One of the first cleft lip and palate candidate gene association studies using a case-control approach provided evidence for the role of transforming growth factor alpha (TGF α) in CL/P.²⁴ [**]

Linkage analysis examines the cosegregation of a disease and a genetic marker in a family unit in order to determine if they segregate independently or together. Genetic linkage studies using from 1 to 40 families^{20, 21, 25} have suggested loci for clefts on chromosomes 4, 6, 17 and 19, but results have been inconsistent¹⁸ with only loci on 6p consistently showing linkage to CL/P in studies from Denmark,²⁶ Italy²⁷ and the UK.²⁸ The UK study, which involved a genome-wide screen carried out on 100 sibling pairs, confirmed nine regions of interest. One of these regions at 1p36 is of particular interest because its deletion is associated with an increased frequency of clefting²⁹ and contains the genes SKI, P73 and MTHFR which are candidate genes for CL/P.¹⁸ There is an expanding list of

Table 77.1 Genetic risks of cleft lip and or palate in the absence of a defined syndrome or Mendelian pattern.

Relationship to index case	Cleft lip with or without palate (%)	Cleft palate alone (%)

genes that have already been shown to play an important role in facial development that includes genes identified as growth factors, cytokines, self-signalling molecules and structural proteins. Gene linkage and association studies have confirmed a possible role for a number of these (Table 77.2).^{24, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40}

ENVIRONMENTAL FACTORS AND GENE/ ENVIRONMENT INTERACTIONS – THE 'GREENSPAN' MODEL

A relation between some environmental factors – notably smoking, alcohol, anticonvulsants, steroids taken during pregnancy and the risk of having a baby with an orofacial cleft is well established. The model for complex diseases presented by Greenspan⁴¹ can be applied to CL/P and CPO both of which have a multifactorial aetiology. According to Greenspan's model, the same output or phenotype can be produced in different ways with a network of interactions, including the type of gene mutation, the effect of other genes and environmental factors. Complex pathways through this network of gene–gene interaction and gene–environment interaction may provide alternative routes through which CL/P and CPO can be developed and avoided. An example of a possible gene–environment interaction important for the development of orofacial clefts is that between folate and the methylenetetrahydrofolate reductase (MTHFR) gene.

The role of folic acid metabolism in the aetiology of orofacial clefting is less clear than that demonstrated for neural tube defects (NTD).⁴² There is conflicting evidence about the beneficial role of dietary folate supplement in preventing orofacial clefts, although the weight of evidence does support the view that there is some benefit if folate is taken periconceptually in high doses.⁴³ Recent studies have indicated a role for folic acid and the MTHFR gene in the aetiology of CL/P, but the strength and direction of this genetic–environment interaction has not been clarified.^{44, 35, 38} The study of gene–environment interactions in orofacial clefting has achieved some remarkable successes and developments in genetic technology promise that such successes are only the beginning.^{45, 46} [**]

CLEFTS AS PART OF A SYNDROME

Most orofacial clefts are nonsyndromic and occur as an isolated anomaly. Additional malformations are more frequently associated with CPO than with CL/P and least of all with isolated cleft lip, but reported rates of associated malformations vary considerably. Recent studies have reported rates of associated anomalies varying between 22 and 47 percent for CPO and 28 and 37 percent for CL/P, similar to previous estimates of 50 percent for CPO and 30 percent for CLP.^{11, 47, 48, 49} Malformations of the upper or lower limbs or the vertebral column are the most common associated anomalies, accounting for 33 percent of all associated defects followed by cardiovascular anomalies which make up 24 percent.⁵⁰ [**]

An increasing number of syndromes with orofacial clefting as part of the spectrum of anomalies has been reported since 1970.⁵¹ There are now over 400 syndromes associated with CPO and CL/P in the London Dysmorphology Database.⁵² Cleft lip and palate and cleft palate only are the most common syndromic cleft subtypes; cleft lip on its own is only rarely syndromic. Syndromic clefts have a variety of causes, including single gene disorders that exhibit Mendelian inheritance, chromosome abnormalities and teratogens. In over 50 craniofacial syndromes a gene has been either mapped to a chromosomal location or actually isolated and its structure identified. In most cases different genes have been responsible for different syndromes but occasionally there are cases where identical mutations produce different syndromes suggesting the influence of other genes or environmental factors. Table 77.3 shows some of the common syndromes associated with clefting.

ROBIN SEQUENCE AND ROBIN COMPLEXES

Pierre Robin sequence is a common condition that includes a combination of micrognathia or retrognathia, cleft palate, glossoptosis (backward prolapse of the tongue) and upper airway obstruction. What is now recognized as Pierre Robin sequence was first described in

Table 77.2 Some of the candidate genes suggested by allelic association and/or linkage analysis for orofacial clefting.

Candidate gene	Gene map locus	Name of gene	Reference
TGF alpha	2P13	Transforming growth factor alpha	21, 30, 31
MSX1	4p16.1	Homeobox gene (HOX7)	31, 32, 33
MTHFR	1p36	Methylenetetrahydrofolate reductase	34, 35, 36, 37, 38
TGF beta 3	14q24	Transforming growth factor beta 3	31, 33

1923 as a 'syndrome consisting of micrognathia and upper airway obstruction'.⁵³ The term 'sequence' denotes a series of anomalies caused by a cascade of events initiated by a single malformation. This is in contrast to the term 'syndrome', which is reserved for those errors of morphogenesis where the simultaneous presence of multiple anomalies can be attributed to a single cause. Robin sequence denotes a cascade of events starting with retrognathia or micrognathia (**Figure 77.7**). The consequent posterior position of the tongue prevents normal elevation of the palatal shelves resulting in a 'U'-shaped cleft palate. Respiratory compromise is produced by true glossoptosis. Because of causal, pathogenetic and phenotypic differences Robin sequences of various types can occur alone or as part of a syndrome, which may be genetically determined.^{54, 55} In many cases of apparent Robin sequence, the manifestations are causally but not sequentially related. For example, the clinical

manifestations of del(22q11.2) or velocardiofacial syndrome include retrognathia (caused by an obtuse cranial base angle), cleft palate (submucous or true) and airway obstruction. In this syndrome the mechanism of airway obstruction, when present, is not caused by retrognathia, but by hypotonia. The term 'Robin complex' has been suggested to describe those cases where the manifestations are causally but not sequentially related.⁵⁶

MANAGEMENT OF CLEFT LIP AND PALATE

Diagnosis

In the past, clefts of the lip and palate were diagnosed at birth. This is still largely true today. One exception is the diagnosis of submucous cleft palate which usually only becomes manifest if and when speech problems, in the form of velopharyngeal insufficiency (VPI), are identified. Diagnosis is often delayed until after the age of three years and sometimes much later. Early identification of submucous cleft palate would allow early treatment before speech problems develop, but this is complicated by the fact that not all cases of submucous cleft cause such problems. The mere presence of a submucous cleft is not in itself an indication for treatment. Careful monitoring of speech development is essential. Identification of feeding difficulties in the neonatal period may be a marker for the subsequent development of VPI.

During the last decade, technological advances in obstetric ultrasound have facilitated prenatal diagnosis of cleft lip and palate. Cleft lip can now be accurately detected by transvaginal sonography as early as 13–16 weeks gestation.⁵⁷ The size and severity of the cleft cannot as yet be accurately assessed. Isolated cleft palate cannot be detected or ruled out prenatally.

Prenatal diagnosis in cleft lip and palate has inevitably raised difficult ethical issues. There is evidence from a study in Israel that the adoption of widespread prenatal screening for cleft lip and palate at 14–16 weeks gestation is associated with a high incidence of termination in cases where a cleft lip has been diagnosed, even in the absence of other major congenital anomalies.⁵⁸ This is in contrast to a study in California where the reported incidence of termination in prenatally diagnosed cleft lip was much smaller at around 10 percent.⁵⁹ Factors that may influence the uptake of termination include the timing of prenatal screening, the perception of the 'burden of clefting', which is influenced by cultural, religious and socioeconomic factors, and the provision of genetic counselling at the time of prenatal diagnosis. It is likely that prenatal diagnosis will have an impact on the incidence of cleft lip and palate in live-born infants in certain countries. This in turn will have an impact on the demand for provision of treatment.

General principles

Management of patients with cleft lip and palate requires a multidisciplinary approach delivered by a team. This will ideally include a nurse specialist, paediatrician, feeding specialist, speech and language therapist, cleft surgeon, orthodontist, audiologist, otolaryngologist and psychologist.

CP/CLP can cause impairment of feeding, hearing, nasal breathing, speech, dentofacial growth and development, facial appearance and psychosocial well-being.^{60, 61}

Table 77.4 lists examples of outcomes associated with facial appearance, growth and function, psychosocial state and patient satisfaction that have been measured by investigators in the field of cleft lip and palate research.

The goal of cleft care is to correct all the problems attributable either directly or indirectly to the original malformation. The burden of prolonged treatment – which often extends over many years and involves multiple surgical procedures – can cause significant disruption to family life.⁶³ [**/*]

Most clinical evidence supporting contemporary treatment regimes for cleft lip and palate is based on case reports and observational studies. This is the case in most if not all surgical disciplines where until recently, studies of operations were retrospective case series with randomized controlled trials accounting for less than 10 percent of the total.^{64, 65} There is little objective evidence to help choose between various treatments. A recent survey of European cleft services revealed that 194 different surgical protocols were performed by 201 teams for unilateral cleft lip and palate alone.⁶⁶

We still do not know for certain what are the best operations, when to do them and what ancillary treatments should be employed.

Early management – airway and feeding

Parents of a child born with cleft lip and palate need psychological support and access to early specialist feeding advice. Babies with cleft lip or cleft lip and palate can experience feeding problems that usually resolve in the early neonatal period. Babies with an isolated cleft palate may continue to experience problems for many months and require careful management.⁶⁷ Palatal obturator plates have enjoyed widespread use, but their popularity has declined in the absence of evidence to show any real benefit.^{68, 69} [****/***] Babies with additional anomalies are at increased risk of feeding problems and may also have difficulty maintaining a satisfactory airway. Pierre Robin sequence is a well-recognized set of anomalies that presents with retrognathia, cleft palate, glossoptosis and varying degrees of upper airway obstruction. Mild cases can be managed conservatively by careful postural management during feeding and sleep. More severe cases may require airway support during the early months of life with a nasopharyngeal tube and nasogastric or gastrostomy feeding.⁷⁰ [**]

Presurgical orthopaedics

Preoperative preparation using presurgical orthopaedics has been used for centuries to try to realign the bony

Table 77.4 Examples of outcome measures used in cleft lip and or palate research.

Variable category	Outcome measure	Method	Data form
Facial appearance	Lip and nose form	Standardized subjective analysis using reference examples, anthropometric analysis, rating specific features or pairwise matching ⁶²	Photographs
Facial growth and development	Facial profile	Cephalometric analysis	X-rays

elements of the cleft and facilitate surgical repair.⁷¹ More recently, appliances have been directed at moulding the alar cartilages of the nose to facilitate primary nasolabial reconstruction.⁷² Active appliances are designed to transfer forces produced by springs, elastic strapping or screws to the bone elements. Passive appliances align segments by channelling growth into prepared spaces underneath an acrylic plate which has to be continuously adjusted, keeping the tongue out of the cleft. Treatment is usually prolonged, requires a high degree of co-operation and can be demanding for parents. There is no doubt that these techniques can in many cases facilitate operative closure of cleft lip and palate, but paradoxically there is no evidence that creating a more normal bone alignment prior to surgery results in an improved surgical outcome. Extravagant claims that presurgical orthopaedics promotes growth have not been substantiated. Current evidence does not support its use as a cost-effective treatment.⁷³ [****]

Expectations from surgery

Improved understanding of the mechanisms of facial growth together with a detailed appreciation of the complex arrangement and function of muscles involved in the cleft lip and palate deformity have contributed to recent advances in surgical care of cleft lip and palate. Enthusiasm for radical surgery has been tempered by an ever-increasing awareness that surgery itself can have a detrimental effect on facial growth. Cleft lip and palate surgery should **aim** to achieve the following:

- isolation of the nasal cavity from the mouth;
- bone continuity throughout the maxillary alveolus to facilitate the eruption of the permanent dentition;
- a functional velum that will permit normal speech;
- an aesthetic and functional lip and nose.

In order to achieve these aims, it is best to restore nasolabial form and function at the earliest opportunity – usually before age six months – and to complete repair of the secondary palate by the time ‘babbling’ has become established – usually before 9–12 months. Bony restoration of the alveolar cleft in order to facilitate eruption of the permanent teeth is usually completed by age 11 years.

In the past, attempts at restoration of nasal form and function were delayed often until age 12 years in order to reduce the risk of growth impairment. Recognition of the importance of nasal breathing and the intimate relationship between form and function of the nose and lip has encouraged an earlier radical approach to nasal repair which is now often attempted at the time of primary lip repair. There is still controversy about the best way to repair a cleft lip and palate. This is largely due to the wide degree of variability in the deformity itself and debate about the relative contribution of inherent tissue hypoplasia and secondary functional hypoplasia.

Traditional methods of lip repair focused on achieving balanced length and proportion of lip skin and vermillion and the production of a symmetrical ‘Cupid’s bow’ by the transposition of skin flaps. A detailed analysis of the skin around the cleft lip deformity shows that it is both retracted and displaced secondary to the initial hypoplasia and a lack of normal muscle function. The skin of the nasal floor, which is quite different from lip skin being thinner and hairless is pulled down into the upper part of the lip.^{74, 75, 76} Respect for these boundaries in the design of skin incisions avoids transposition of nasal skin on to the lip. Incisions should ideally not cross aesthetic boundaries such as the alar and columellar bases. The length of the repaired cleft lip is influenced to a large degree by underlying muscle function. It is now recognized that optimum results can only be consistently achieved if a detailed nasolabial muscle repair is performed.^{77, 78, 79, 80} [**/*] The nasolabial muscle rings are disrupted in complete cleft lip deformity and their abnormal insertions result in unbalanced muscle function, which further worsens the degree of deformity (Figure 77.8).

Timing of surgery

Operative procedures for cleft lip and palate can be categorized into primary and secondary procedures depending on the timing of intervention. Primary procedures include repair of the cleft lip/nose and palate deformity and repair of the alveolar bone defect with or without alveolar bone grafting. Secondary or revision procedures are often directed at improving speech. They include fistula repair, soft palate revision surgery,

© Hodder Arnold / Scott-Brown 7E

Figure 77.8 Nasolabial muscle ring in unilateral cleft lip. M, myrtiform head of nasalis muscle; O, oblique head of orbicularis oris; T, transverse head of nasalis muscle.

pharyngoplasty, posterior pharyngeal wall implant, secondary or revision surgery to the lip/nose complex and orthognathic surgery.

Timing of lip repair varies from a few days to six months according to the surgeon's preference. Some surgeons carry out neonatal repair, but as yet there is no clear evidence to justify the increased risk of surgery at this age. It is difficult to carry out detailed muscle reconstruction before three months of age. Some surgeons perform preliminary 'lip adhesion' (which essentially involves joining the skin and leaving the muscle alone at the margins of the cleft) on wide clefts to try to reduce the size of the cleft prior to a definitive repair.⁸¹ There is no evidence to show that this contributes to improved outcomes, but some surgeons still use it as an alternative to preoperative orthopaedics.

Table 77.5 outlines the timing of surgical procedures performed in the treatment of cleft lip and palate.

Unilateral cleft lip

Various flaps involving rotation, advancement and triangular designs have been and are used in the repair of unilateral cleft lip (Figure 77.9).^{82, 83} The most popular is the rotation advancement technique first described by Millard in 1976 (Figure 77.10).⁸² Numerous modifications of Millard's original design have since been proposed, including measures to lengthen the columella and reduce scarring across the columella base.⁸⁴ Delaire has described a design that respects the anatomical boundaries between lip and nasal skin and avoids crossing aesthetically sensitive areas, such as the columella base and alar rim (Figure 77.11). Although this incision in itself has little facility to lengthen the lip, the incorporation of wavy lines and small triangular flaps above the vermillion allow some degree of lengthening. Delaire emphasizes the important contribution that the restoration of labiomaxillary muscle function makes towards achieving satisfactory lip length and aesthetics.^{74, 75, 76} and considers this to be as important as

geometric arrangement of skin flaps (Figure 77.12). [**/*] Some postoperative support is required to maintain the nasal correction. This can take the form of nasal splinting⁷⁹ or internal support sutures.⁸⁵

		Variable
Secondary/revision surgery to lip/nose		Variable
Orthognathic surgery		>17 years

Figure 77.11 (a,b) Incision design for modified Delaire-type repair of complete unilateral cleft lip.

Figure 77.12 Repair of the nasolabial muscle ring in complete unilateral cleft lip.

Bilateral cleft lip

Bilateral cleft lip (**Figure 77.13**) is a more severe deformity than unilateral. There is often a significant degree of hypoplasia in the midline prolabium, which is bereft of muscle and normal vermillion. The short columella, which characterizes bilateral clefts is seldom fully corrected by functional surgery alone. A characteristic feature of complete bilateral clefts is the marked projection of the prolabium and premaxilla, which further compounds the surgical problem. Lip adhesions and presurgical orthopaedics in the form of lip strapping are often employed to lessen the degree of projection and facilitate primary lip repair.

Restoration of labiomaxillary muscle function helps achieve satisfactory lip length and aesthetics, but achieving muscle continuity across the prolabium can be difficult. Lip adhesion has been advocated as a primary procedure in order to facilitate the muscle repair at a second operation. Alternatively, a two-stage procedure repairing one side at a time can be carried out, although it has the disadvantage of introducing a degree of asymmetry into what was otherwise a symmetrical deformity. There is little evidence to support the use of

Figure 77.13 Complete bilateral cleft lip.

either of these approaches. An example of a single-stage surgical approach which facilitates labiomaxillary muscle reconstruction and nasal dome reshaping is shown in **Figure 77.14**.

The management of the short columella is controversial. Techniques have been devised which import skin from the prolabium or nasal sill into the columella to provide length. An example of this approach is the elevation of forked flaps from the sides of the prolabium, which are initially stored in the nasal sill and then elevated into the columella at a second-stage operation.^{86,87} The disadvantage of this technique is that it produces unsightly scars under the columella and an unnatural appearance to the external nares, which often appears overtly large. The latter problem is a consequence of ignoring the real nature of the alar cartilage deformity. The domes of the alar cartilages are grossly flattened, but the cartilage itself is seldom hypoplastic. The shortened medial element is compensated by increased length of the lateral element – the effect of which is to drag the columella ‘into the nose’. Importing tissue into the columella magnifies this aspect of the deformity. A better approach is to retrieve the columella from where it has been hidden in the nose and correct the imbalance between the medial and lateral elements of the alar cartilage. This requires careful dissection under and between the domes of the lower alar cartilage (**Figure 77.14c**). The lower alar cartilage is released from the mucosa and overlying skin, repositioned and supported by direct suturing or long-term nasal splints.⁸⁸ Nasolabial moulding is a form of presurgical orthopaedics that expands the columella preoperatively. This facilitates correction of the nasal tip cartilages through a retrograde approach under the prolabium and columella.⁸⁹ [*/*]

Alveolar cleft

It is important to repair the alveolar cleft and to achieve bone continuity in order to create an intact alveolar arch

© Hodder Arnold / Scott-Brown 7E

and to allow eruption of the lateral incisor and canine. There are **two main ways** in which this can be achieved.

1. **Secondary alveolar bone grafting at age 9–11 years (Figure 77.15).** This is often preceded by primary soft-tissue closure with a vomer flap at the time of primary lip repair, although the alveolar cleft may be left unrepaired at the time of primary surgery.
2. **Primary gingivo-periosteoplasty (GPP) at either the time of palate closure or delayed until the age of three to five years.**

There is good evidence that secondary alveolar bone grafting produces consistently good results.^{90,91} [**/*] Timing of the bone graft is usually determined by the development of the canine tooth, although earlier bone grafting may be indicated to support the eruption of the lateral incisor. **There is no evidence that secondary bone grafting has a detrimental effect on facial growth when performed between 9 and 11 years of age.** This is in contrast with primary bone grafting carried out before two to three years of age where evidence from retrospective case series suggests that these early bone grafts were associated with significant growth impairment.^{92,93} [**/*]

The concept of stimulating bone growth in the alveolar cleft underneath transposed mucoperiosteal flaps (gingivo-periosteoplasty) has been around for many years. It has the obvious advantage of removing the need for a later bone graft and has the potential for establishing an intact alveolus at a much earlier age than secondary bone grafting. GPP is carried out before three years of age and often at the time of primary palate repair. Success depends on achieving approximation of the alveolar segments, which usually requires some form of presurgical orthopaedics. There is concern that early surgery on the alveolus may impair maxillary growth,⁹⁴ but preliminary results have been encouraging.^{95,96,97} [**] The results of treatment after completion of facial growth are awaited before the efficacy of this technique can be confirmed.

Figure 77.15 Incision design for secondary alveolar bone graft.

Hard palate repair

Palate repair has invoked **much controversy over the years mainly because of the detrimental effect that palatal surgery has on maxillary growth.** Traditional methods of closure involve **transposition of either bipedicle flaps (Langenbeck flap) or axial flaps based on the greater palatine vessels (Veau flap, Veau–Wardill–Kilner).** These methods can be used to repair the hard and soft palate (secondary palate) cleft in one stage (**Figure 77.16**). It is now recognized that scars formed by leaving areas of exposed bone in the hard palate, especially the anterior and lateral margins of the palate produced by ‘push back procedures’, have the potential to inhibit both anterior and transverse growth of the maxilla.⁹⁸ [**/*] Modifications of the Langenbeck flap have been introduced whereby the flap is designed inside the greater palatine pedicle in order to move the area of denuded palatal bone

© Hodder Arnold / Scott-Brown 7E

Figure 77.16 Methods of cleft palate repair: (a,b) Langenbeck; (c,d) Veau; (e,f) Veau-Wardill-Kilner.

more medially. There is, however, no evidence other than occasional case series using historical controls to suggest that this approach has any benefit.⁹⁹ [*//*] Two other strategies designed to lessen the impact of palatal surgery on facial growth include delayed closure of the hard palate and the vomer flap. In delayed closure, the soft palate is repaired at the usual time around six to nine months of age, but no attempt is made to repair the hard palate. **Delaying hard palate closure for a number of years results in a reduction in the width of the cleft and facilitates repair without the need for transposed palatal flaps.** (Figure 77.17).⁷⁶ The main objection to this approach is the detrimental effect that delay in hard palate closure beyond 12–18 months may have on speech development, in addition to the problems associated with a persistent hard palate fistula.

The use of a vomer flap to repair the hard palate cleft was first described by Pichler in 1926.¹⁰⁰ Used as a single layer closure, the periosteal surface of the flap is

transposed to the palatal side where it becomes epithelialized leaving a large part of the vomer exposed to heal by secondary intention (Figure 77.18). Alternatively, it can be used as part of a two-layer closure. The main objection to this method is that **like traditional palatal flap repairs, the transposed vomer flap may have a negative impact on maxillary growth.**¹⁰¹ [*] This would seem to be a logical expectation, but evidence from analysis of case series from the Oslo group in particular show that it has only a minimal effect, if any, on anterior maxillary growth.⁹¹ [**] The effect on vertical maxillary growth is less clear and needs to be confirmed by further research.

Anatomy and function of the soft palate

An understanding of normal soft palate anatomy is fundamental to achieving a satisfactory muscle

© Hodder Arnold / Scott-Brown 7E

Figure 77.17 Two-stage method of cleft palate repair: (a) incision design for soft palate repair; (b) wound closure of soft palate repair; (c) medial Langenbeck incision design for second-stage hard palate repair; (d) wound closure of hard palate repair. After Delaire.⁷⁶

reconstruction (**Figure 77.19**). A fibrous aponeurosis occupies the anterior third of the velum. It is attached to the posterior edge of the hard palate and is continuous with the tendon of tensor veli palatini. The tensor tendon

winds around the hamulus to which it is partly attached and ascends to its origin in the scaphoid fossa, spine of the sphenoid bone and membranous portion of the tympanic tube. It is this latter attachment which suggests that the tensor's primary function is related to Eustachian tube function rather than velar function. The primary velar muscles are the levator palatini, palatopharyngeus and palatoglossus. The palatoglossus and palatopharyngeus arise from the back of the palatal aponeurosis and maxillary tuberosity. The palatoglossus is a thin sheet of muscle that extends to form the anterior pillar of the fauces. The palatopharyngeus is a much more substantial muscle that is split into two heads by the insertion of the levator palatini and runs down to form the posterior pillar of fauces and inserts into the thyroid cartilage and pharyngeal aponeurosis. The levator palatini muscle originates from the medial part of the Eustachian tube and from the petrous temporal bone. It runs down forwards and medially to enter the middle third of the velum between the two heads of palatopharyngeus to join with its partner from the opposite side. It is the prime elevator of the velum. The palatopharyngeus and palatoglossus act as depressors and all three muscles act to lengthen the velum. The last muscle to consider is the muscularis uvulae, which runs anteroposteriorly from the posterior nasal spine to the uvula beneath the nasal mucosa. The function of the muscularis uvulae remains unknown.

The mechanism of velopharyngeal function has been studied qualitatively by nasendoscopy and both qualitatively and quantitatively by videofluoroscopy.^{102, 103, 104} Movement of both the velum and pharyngeal walls contribute to normal velopharyngeal function. The pattern of closure differs between individuals and between different speech sounds. Closure during swallowing is much slower and occurs at a lower level in the pharynx than that which occurs during speech.

© Hodder Arnold / Scott-Brown 7E

Figure 77.18 (a,b,c) Vomer flap repair of unilateral cleft palate.

Figure 77.19 Velum muscles: (a) sagittal view from midline; (b) inferior view. LP, levator palatini; PP, palatopharyngeus; SP, superior constrictor; TP, tensor palatini.

Anatomical variables which affect velopharyngeal closure include:

- the size of the velum in relation to the depth and width of the oropharynx and the slope of the posterior pharyngeal wall. The area of contact between the velum and posterior pharyngeal wall includes adenoid tissue, which can make an important contribution to velopharyngeal closure.¹⁰⁵ [***]
- the extensibility of the velum;
- the degree of lift of the velum.

Soft palate repair

The goal of soft palate repair is to achieve velopharyngeal competence. Early attempts at repairing the soft palate were limited to achieving surgical closure of the cleft by joining the muscle and mucosa at the margin of the cleft. Later attempts at lengthening the soft palate with 'push back' procedures not only failed to achieve extra length, but also left large areas of denuded bone in the anterior hard palate, which had a detrimental effect on growth.⁹⁸ [**] More recently, surgeons have attempted to address the underlying muscle abnormality in an attempt to create a levator sling imparting improved function to the velum. The cleft muscle deformity was first described by Veau² and has since been elaborated on by several authors.¹⁰⁶ In cleft palate, the tensor aponeurosis is thickened into a fan shape that inserts into the lateral part of the posterior edge of the hard palate. The levator palatini and palatopharyngeus being unable to meet in the midline run forward to insert into the medial part of

the posterior edge of the hard palate, as well as into the edge of the contracted aponeurosis (**Figure 77.20**).

Various methods of surgical repair that attempt to posteriorly reposition and repair the abnormal velar muscles have been described. Furlow¹⁰⁷ described a novel approach to soft palate repair which incorporated a double opposing 'Z plasty'. This method results in posterior repositioning of the velar muscles, albeit with a degree of asymmetry, and results in some degree of

Figure 77.20 Cleft palate muscles. LP, levator palatini; PP, palatopharyngeus; TP, tensor palatini.

palatal lengthening. Good speech results have been reported using this technique¹⁰⁸ and it has become a popular method of soft palate repair. [**]

Other authors have primarily focused on muscle repair as a way of lengthening the velum.^{109, 110, 111, 112} The first step in muscle repair of the cleft velum is to separate the abnormal attachment of the aponeurosis and muscles from the posterior edge of the hard palate. The muscles are then dissected from their attachment to the nasal and oral mucosa and reorientated to a varying degree. Despite initial enthusiasm, significant improvement in velopharyngeal function following muscle repair has not been unequivocally demonstrated by prospective studies.¹⁰⁹ [**] There is some confusion, however, as to what constitutes an anatomical muscle repair and the degree to which the levator muscle, rather than the palatopharyngeus muscle, is dissected and reorientated. The efficacy of a radical approach to velar repair, which includes dissection and repair of both the levator and palatopharyngeus muscle aided by the operating microscope, has been recently demonstrated by Sommerlad in a prospective case series.¹¹¹ [**]

Secondary surgery – lip, nose and alveolus

Although the benefits of secondary surgery may seem obvious to clinicians, the views of the patient should ultimately determine whether such procedures are carried out. Secondary surgery is often required to correct those problems that were not managed adequately by primary operations. Secondary procedures may be indicated for functional and aesthetic correction of the lip and nose, to close palatal fistulas and to correct velopharyngeal incompetence.

Lip and nose procedures may vary from simple procedures to align the vermilion or lengthen the lip scar to complete revision of the lip and nose encompassing muscle reconstruction and nasal correction. The secondary unilateral cleft nose deformity is characterized by an asymmetric nasal tip, deviated septum and asymmetry of the nasal bones. The secondary bilateral cleft nose deformity is usually characterized by a short columella and wide alar base. Complete correction of these deformities is facilitated by an open approach to the nasal tip. This technique allows direct visualization and correction of the alar cartilage deformity. Attention to the bone deformity is usually delayed until after ten years of age. [**/*]

Palatal fistula

Palatal fistulas can occur as a result of wound breakdown at the time of hard palate repair. They usually occur just behind the alveolus or at the junction between the hard and soft palate. Palatal fistulas that are causing problems with

speech or nasal regurgitation can be repaired at any age, but the success of the secondary repair is adversely affected by scarring from the primary procedure. Those fistulas near an alveolar cleft can usually be left until bone grafting is carried out at nine to ten years of age. Most fistulas can be closed by local flaps. Large fistulas may require tissue to be imported from elsewhere, such as a tongue flap.

OTITIS MEDIA IN CLEFT PALATE

Eustachian tube dysfunction is almost universal in children with cleft palate.¹¹³ The majority will demonstrate some evidence of otopathology, most frequently otitis media with effusion (OME) (see Chapter 72, Otitis media with effusion). Sensorineural hearing loss is also more common in this group of children.¹¹⁴ Cholesteatoma and conductive hearing loss persisting into adult life are more prevalent than in age-matched controls.^{115, 116} [**] This tendency to develop OME is not reversed by early palatal surgery and children should have careful ENT and audiological surveillance even after the palate has been repaired.

Management strategies for otitis media in cleft palate children vary among different teams. Most clinicians agree on the need for a concerted multidisciplinary approach.¹¹⁷ Some teams feel that the frequency of OME in cleft palate is such as to warrant early tympanostomy tubes and report good audiological outcomes.¹¹⁸ [**] The alternative approach is to offer tympanostomy tubes only when there is overt evidence of OME.¹¹⁹ The provision of hearing aids is increasingly considered, avoiding the morbidity associated with often-multiple grommets.¹²⁰ Long-stay tympanostomy tubes are associated with even higher complication rates, notably persistent perforation of the tympanic membrane (see Chapter 72, Otitis media with effusion).

The optimum approach is unknown. Current advice is that cleft palate teams should ensure careful otological and audiological surveillance of all cleft palate children with intervention as appropriate for each child.

Velopharyngeal insufficiency

PATHOPHYSIOLOGY AND ASSESSMENT

Velopharyngeal insufficiency (VPI) is an inability to completely close the velopharyngeal port during speech. This results in leakage of air into the nasal cavity and produces hypernasal vocal resonance and nasal air emission. Patients with VPI may develop compensatory misarticulations, which can be difficult to resolve even if the VPI is corrected. Causes include:

- cleft palate;
- submucous cleft palate;
- congenital or acquired neuromuscular abnormalities;

- iatrogenic;
- adenoidectomy;
- palatopharyngoplasty for sleep apnoea;
- maxillary advancement procedures;
- unknown.

Cleft palate is the most common cause, but any congenital or acquired condition that interferes with velopharyngeal closure can result in VPI.

The incidence of post-adenoidectomy VPI is about 1/1200 and often occurs because underlying pathology such as submucous cleft palate becomes unmasked.¹²¹ [**] It is important to examine patients for stigmata of submucous cleft palate, i.e. bifid uvula, before adenoidectomy is performed. Occasionally a remnant of adenoid tissue forms an irregularity in the posterior pharyngeal wall. Large tonsils occasionally obstruct velopharyngeal closure. VPI occurring after adenoidectomy will spontaneously resolve in about 50 percent of cases.¹²¹ [**] Therapeutic measures used to treat VPI include speech and language therapy, surgery, a prosthetic obturator or palatal lift appliances. The choice of therapy will depend on a number of factors including aetiology of the VPI, age of the patient, length of time VPI has been present and the presence of articulatory compensations.

A specialist speech and language therapy assessment is an essential first step in diagnosis. This can be supported by airflow/pressure studies and acoustic analysis. Videofluoroscopy and nasendoscopy provide useful information about the structure and dynamics of the velopharyngeal mechanism. Videofluoroscopy involves a significant radiation dose and co-operation may be a problem with nasendoscopy especially in young children. Magnetic resonance imaging (MRI) may offer a solution in the future, but image acquisition is too slow for real-time studies at present.

PALATE REPAIR

Surgery to improve velar length and function may be indicated especially where there is evidence of anterior insertion of the levator muscles, or in the case of a submucous cleft. Palate rerepair in the form of a radical intravelar veloplasty or Furlow double opposing 'Z' plasty has been shown to be effective in treating VPI following cleft palate repair in selected cases where the velopharyngeal gap is small.^{122, 123} [**] These procedures have a lower morbidity than a pharyngoplasty.¹²⁴ [***]

Pharyngoplasty

In those patients where palate rerepair is not appropriate or is unsuccessful, surgery to alter the form and function of the pharyngeal wall may be considered. Augmenting the posterior wall with an implant is perhaps the simplest method, but the outcomes are often unsatisfactory and extrusion of the implant is common.¹²⁵ [**] The alternative is a pharyngoplasty. There are two main types

of pharyngoplasty: those employing medial transposition of flaps from the lateral pharyngeal wall and those that employ flaps from the midline of the pharyngeal wall. In lateral flap pharyngoplasty (Figure 77.21), muscle flaps derived from the posterior pillar of the fauces can be used to augment the posterior and lateral walls of the pharynx and decrease the velopharyngeal gap. If the nerve supply to these flaps is preserved they may also remain contractile, providing a sphincteric closure. In the Hynes type of pharyngoplasty, flaps from the posterior pillar of the fauces containing palatopharyngeus and salpingopharyngeus are inserted as high as possible in the posterior pharyngeal wall at the projected level of contact with the velum.¹²⁶ This usually necessitates division of the posterior part of the velum to provide access. In another type of lateral flap pharyngoplasty, described by Orticochoea,¹²⁷ the flaps are inserted lower down below the projected point of contact with the velum. Insertion of the flaps into the posterior pharyngeal wall is assisted by the elevation of a small posterior pharyngeal flap. The success of this procedure is dependent on active contraction of the transposed palatopharyngeus muscle. A number of reports have found a correlation between the level of flap insertion and improvement in nasalance scores during speech. Several authors have concluded that the flaps should be placed as high as possible in the nasopharynx at the point of velopharyngeal contact,^{128, 129} similar to the procedure originally described by Hynes. [**/*]

Midline flap pharyngoplasty involves inserting an inferiorly or more commonly a superiorly based flap (Figure 77.22) from the posterior pharyngeal wall into the posterior edge of the velum.^{130, 131} The flap forms a static bridge with lateral ports on either side that are closed by medial movement of the lateral pharyngeal walls. Shrinkage of the flap occurs to a variable degree. Lining the flap as much as possible with nasal mucosa can minimize this. Midline flaps are entirely static and rely on lateral wall movement to effect closure. If there is no lateral wall movement, velopharyngeal competence can only be achieved by making the flaps so wide that they obstruct the nasopharynx. In contrast, the effectiveness of lateral flap pharyngoplasty is dependent on sphincteric contraction of the flaps themselves, as well as movement of the velum.

It would seem logical that the choice of operation should be guided by the preoperative pattern of closure. This approach has been supported by some prospective studies which show that it is possible to achieve normal resonance in up to 85 percent of cases.^{132, 133, 134} [***/*] However, a recent randomized controlled trial comparing sphincter pharyngoplasty to a pharyngeal flap has failed to show a difference in speech outcome between the two types of procedure.¹³⁵ [****]

Complications of pharyngoplasty

Common side effects of pharyngoplasty include snoring, mouth breathing, catarrh and nasal obstruction. A less

common but more serious side effect is obstructive sleep apnoea (OSA) which has a reported incidence ranging between 4 and 90 percent and can occur in all types of pharyngoplasty.^{135, 136} [****/****/**] The large range in the reported incidence of OSA probably reflects the different measurement protocols used to diagnose OSA, as well as patient and operative variables. There is evidence from the VPI surgical trial group that severity of OSA tends to decrease with time so that by 12 months post-operation significant OSA is rare irrespective of the type of pharyngoplasty.¹³⁵ [****]

Our incomplete understanding of the side effects represents a significant limitation when advising patients on the risks and benefits of surgery for VPI, especially in patients with mild symptoms.

KEY POINTS

- Clefts of the lip and palate are common congenital birth anomalies.
- Aetiology is complex. Known associations are with antenatal anticonvulsants, steroids, maternal smoking and alcohol. Some of the genes associated with orofacial clefting have now been identified.
- Prenatal screening for cleft lip is now routinely available in many centres.
- Management of patients with cleft lip and palate requires a multidisciplinary approach delivered by a team which includes an otolaryngologist.
- Otitis media is a significant problem in cleft palate children and requires careful surveillance and management.
- Eustachian tubal dysfunction and otitis media with effusion are almost universal in cleft palate children.
- Minor abnormalities of palatal function may cause velopharyngeal insufficiency with an adverse effect on the child's speech.

Best clinical practice

- ✓ In Pierre Robin sequence, severe cases may require airway support during the early months of life with a nasopharyngeal tube. A tracheostomy is nowadays very rarely required. [Grade C/D]
- ✓ Palatal obturator plates have enjoyed widespread use, but their popularity has declined in the absence of evidence to show any real benefit. [Grade B]
- ✓ Extravagant claims that presurgical orthopaedics promotes growth have not been substantiated.

Current evidence does not support its use as a cost-effective treatment. [Grade A]

- ✓ Optimum management of otitis media should be customized to the individual child. Ventilating tubes are not always appropriate. [Grade B]
- ✓ Otolaryngologists need to be particularly vigilant in recognizing submucous cleft palate. [Grade C/D]
- ✓ The mere presence of a submucous cleft is not in itself an indication for treatment. [Grade B]
- ✓ Careful monitoring of speech development is essential in submucous cleft. [Grade C/D]
- ✓ Otological and audiological surveillance is an essential part of the management of cleft palate. Children with hearing loss require active intervention and support with a management strategy and treatment plan established for each child. [Grade C/D]
- ✓ Many cases of velopharyngeal insufficiency occurring after adenoidectomy can be treated expectantly. [Grade C/D]

Deficiencies in current knowledge and areas for future research

- Advances in genetics are helping to unravel the aetiology of orofacial clefting. Many candidate genes are now being sequenced.
- Reorganization of cleft palate services and the concentration of expertise in centres where a multidisciplinary team is available has the potential to improve data collection, clinical audit and research, as well as outcomes for cleft palate children in the UK.
- Dedicated training in cleft palate surgery is likely to improve outcomes further.
- The optimum management of OME in cleft palate is unknown. Centralized collection and analysis of data from the many teams looking after these children with careful monitoring of otological and audiological outcomes would greatly help rationalize treatment planning.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words craniofacial anomalies, craniosynostosis, hemifacial microsomia, Treacher Collins syndrome, encephalocoele and craniofacial clefts.

INTRODUCTION

The term 'craniofacial anomalies' encompasses a large number of different conditions, usually present at birth, and variable in their aetiology, extent, severity and clinical presentation. Different terminologies, classification systems and treatment protocols can add difficulties for those trying to gain an understanding of the subject. Management usually requires multidisciplinary input and coordination, often from a large number of different specialists working as part of a dedicated craniofacial team. For many conditions, monitoring and intervention is required from birth to maturity and often beyond, well into adult life. The aim of this chapter is to describe some of the more commonly encountered groups of craniofacial anomalies, to outline the principles of their management, and review the contribution of genetics to the understanding of these conditions.

GENERAL PRINCIPLES OF MANAGEMENT

The craniofacial region is particularly complex in its anatomy and function, evidenced by the large number of

medical and surgical specialities, and professions allied to medicine, that are devoted to this anatomical area. All of these specialists have key roles to play in the management of patients with craniofacial anomalies. The systemic consequences of localized functional impairment in craniofacial anomalies, as well as the frequent presence of associated (noncraniofacial) anomalies, require the expertise of a wide variety of other specialists. Management of paediatric craniofacial anomalies requires all the facilities and expertise available in a modern dedicated paediatric setting.

All patients require screening/assessment by the core members of the team, followed by further in-depth assessment (if necessary by other specialists) and treatment if indicated (see **Table 78.1**). [*]

CLASSIFICATION

Owing to the complexity and heterogeneity of craniofacial anomalies there is no universal classification system. Many classification systems have been proposed, based on embryology, aetiology, anatomical location, morphology and genetics. In England, the National Specialist

Table 78.1 Multidisciplinary team: the roles of each discipline.

Discipline	Role
Genetics	Diagnosis, associated conditions, risk of future siblings having the condition, risk of patient passing on the condition to his/her children
SALT	Speech and language, feeding, general developmental milestones
Psychologist	Parental anxiety, preparation for operations, intervention for older patients, coping strategies, cognitive assessment
Paediatrician	General development, associated abnormalities
Ophthalmology	ICP, acuity and motility
ENT	Airway problems, hearing and middle ear disease
Neurosurgery	ICP, hydrocephalus, associated abnormalities, surgical treatment of the condition
Maxillofacial	Surgical correction of deformity
Plastic surgery	Surgical correction of deformity
Orthodontist	Craniofacial growth and development, dental condition and occlusion
Anaesthetist	Experience of paediatric craniofacial and neurosurgical anaesthesia. Access to paediatric intensive care unit (PICU)

SALT, Speech and language therapist.

Commissioning Advisory Group (NSCAG) recognize six categories of patients:¹

1. craniofacial clefts;
2. craniofacial dysostosis;
3. craniosynostosis;
4. encephalocoele;
5. overgrowth, undergrowth or dysraphia associated with unilateral or bilateral orbital dystopia or displacement;
6. any other complex anomaly where referring specialists feel that the expertise present within the service would substantially benefit the treatment of the condition.

For the purposes of this chapter we present the most common conditions that present to the craniofacial surgeon.

CRANIOSYNOSTOSIS

Craniosynostosis is the term applied to the premature fusion of one or more of the sutures of the growing cranium, and manifests as abnormal cranial growth. In order to understand the pathophysiology of craniosynostosis, normal skull growth must be considered.

Normal skull growth

The stimulus for growth of the cranium comes from the expanding brain, which grows rapidly in the first two years of life, doubling in weight in the first year and achieving 90 percent of its adult size by the age of two years. This rapid brain growth has to be accommodated by a concomitant expansion in volume of the skull. The cranial vault consists of the frontal, parietal, temporal and occipital bones, which are separated from each other by the cranial sutures (metopic, sagittal, coronal and

lambdoid). These sutures allow gradual displacement of the individual bones, allowing the brain to expand. In order to avoid large gaps developing between the bones as the expansion proceeds, new bone is deposited at the free margins of the bones adjacent to the sutures. Bone resorption and deposition also takes place on the inner and outer surfaces of the calvarial bones to produce changes in their curvature and thickness.

The patent cranial sutures therefore allow for growth to take place in response to the stimulus of the growing brain and, unlike the epiphyseal plates of the long bones, cranial bones do not have intrinsic growth potential. The sutures only remain patent while brain growth is taking place. If brain growth ceases, cranial growth ceases, and the cranial sutures will be replaced by bone, resulting in fusion – a normal phenomenon once growth is complete.

Classification

Premature fusion of calvarial sutures has a variety of underlying causes, broadly divided into **primary** and **secondary** craniosynostosis.²

Secondary craniosynostosis is uncommon, but may be seen in microcephaly, where there is a lack of underlying brain growth, in some haematologic (polycythaemia, thalassaemia) and metabolic abnormalities (rickets, hyperthyroidism), and may be drug induced (retinoic acid).

Primary craniosynostosis is much commoner than secondary craniosynostosis. It can be classified on the basis of the number of sutures involved (single suture, multiple or total), the site of the involved suture(s) (metopic, coronal, sagittal, lambdoid) and whether it is an isolated condition (nonsyndromic) or associated with other malformations (syndromic). Primary craniosynostosis constitutes a significant workload in craniofacial units.

Incidence

Primary nonsyndromic craniosynostosis occurs in approximately 1:2000 live births. Of the nonsyndromic craniosynostoses, sagittal synostosis is the most common accounting for 60 percent of cases. In cases of nonsyndromic craniosynostosis there is a male predominance with male to female ratios of 4:1 in sagittal synostosis and 3:1 in metopic synostosis. Of the syndromic craniosynostoses, Crouzon syndrome has the highest incidence with 1:25,000 live births³ and Apert syndrome is 1:60,000 live births.⁴

Aetiology

Craniosynostosis is aetiologically heterogeneous.⁴ Both nonsyndromic and syndromic craniosynostoses result from an interaction between genetic factors, molecular and cellular events, mechanical and deformational forces and secondary effects of each of these on normal growth and development. Premature fusion of the sutures may take place alone or, in syndromic craniosynostosis, with other anomalies. Most cases of isolated craniosynostosis are sporadic. However, familial cases do happen and a positive family history can be found in 14.4 percent of coronal, 6 percent of sagittal and 5.6 percent of metopic synostosis cases, but very rarely in lambdoid synostosis.^{5, 6, 7, 8, 9} For isolated, single suture synostosis with unaffected parents, the recurrence risks range from 1 percent in sagittal synostosis to 5 percent in coronal and metopic synostosis.¹⁰

Chromosomal abnormalities may also cause craniosynostosis, particularly in patients with other anomalies or problems with growth or development. Teratogens may also be causative, as in the case of sodium valproate and trigonocephaly. The syndromic craniosynostoses are usually genetically determined, often occurring as new mutations. There is an increasing recognition that some of the so-called isolated nonsyndromic synostoses also have a genetic basis.

Genetics of craniofacial anomalies

The vast array of genetic conditions causing craniofacial anomalies precludes an exhaustive discussion of their genetics in this text. However, it is appropriate to discuss the more common conditions and encourage a low threshold for the involvement of the clinical genetics team in the management of patients with craniofacial anomalies. Clinical geneticists can contribute to both diagnosis and counselling of affected individuals and also their families. Interested readers are encouraged to consult the texts of Gorlin *et al.*¹¹ and Cohen and MacLean⁴ for more extensive details on craniofacial anomaly syndromes.

When considering the aetiology of craniofacial anomalies it is helpful to consider their aetiology in terms of **malformations** (e.g. genetic syndromes, teratogens), **deformations** (e.g. positional plagiocephaly) and **disruptions** (e.g. amniotic bands). Some craniofacial anomalies are multifactorial.

Genetic testing is not indicated in patients with isolated sagittal or metopic synostosis, in whom there are no associated abnormalities or concerns about growth or development, and no significant family history. However, coronal synostosis, even when isolated, warrants analysis of at least FGFR3 for the Pro250Arg mutation (see below under FGFR3-associated coronal synostosis syndrome – Muenke craniosynostosis) and possibly analysis of the TWIST gene (see below under Saethre-Chotzen syndrome).

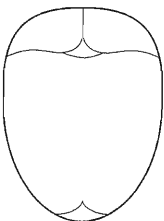

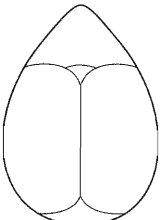

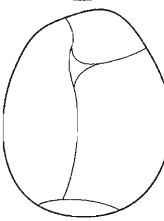

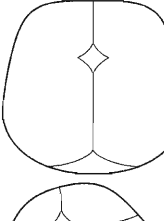

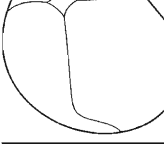

Genetic testing by DNA analysis of specific genes is available only for syndromes where the causative gene has been identified. This facilitates diagnosis and also counselling of family members, particularly when a parent may be a gene carrier with a very mild phenotype. Chromosomal analysis should be considered in any patient with complex or multiple abnormalities, or in whom there are concerns regarding a child's growth or development. Informed consent should be obtained prior to any genetic testing, especially as abnormal results may have implications for other family members as well as the child. Failure to identify a genetic abnormality in a syndromic patient does not, however, rule out a genetic cause for their condition, and involvement of a clinical geneticist is essential.

Prenatal diagnosis by genetic analysis of chorionic villus sample or amniotic fluid may be available for conditions in which the causative genetic abnormality is known. Prenatal ultrasound scanning later in pregnancy may reveal abnormal craniofacial contour or associated skeletal or systemic abnormalities in syndromic conditions; however, the premature sutural fusion of isolated craniosynostosis is much more difficult to detect.

Pathogenesis and consequences

Premature suture fusion results in inhibition of skull growth in a direction perpendicular to the affected suture. Despite this localized failure of skull growth, the brain continues to grow, and expands in different directions, where expansion can be accommodated by normal (patent) sutures, producing compensatory changes at a distance from the abnormal suture and usually parallel to it.¹² In the latter half of the last century, Moss¹³ postulated that the cranial base was the site of abnormal physical stresses, and that these could be transmitted to the dura of the cranial vault, resulting in suture fusion. [**/*/*] Whatever the underlying mechanism, the restriction of growth perpendicular to the fused suture, and the compensatory changes elsewhere in the cranium,

Table 78.2 The craniosynostoses. Affected sutures and resultant head shapes. The anterior aspect of the skull (the forehead) is towards the top of the table.

Shape of skull	Suture affected	Name
	Sagittal	Scaphocephaly
	Metopic	Trigonocephaly
	Unilateral coronal	Frontal plagiocephaly
	Bilateral coronal	Brachycephaly
	Unilateral lambdoid	True posterior synostotic plagiocephaly

may result in a reduction in cranial volume (and hence raised intracranial pressure (ICP)) and a change in shape (resulting in characteristic changes dependent on the suture or sutures involved) (see **Table 78.2**).

Clinical assessment

The history may be of a baby with an abnormal head shape, present at birth, gradually becoming worse. Examination reveals the characteristic head shape (see **Table 78.2**) with ridging of the affected suture.

Imaging

Plain films allow assessment of sutural patency and the overall morphology of the skull. All sutures are easily

visible in the normal growing skull, with the exception of the metopic suture which normally fuses early. A prematurely fused suture may be sclerotic (**Figure 78.1**) or may not be visible at all. The abnormal shape of the head will be apparent, and skull base abnormalities not apparent on clinical examination may be seen (e.g. the ‘harlequin eye’ appearance of the sphenoid ridge in coronal synostosis). Computed tomography (CT), especially when reconstituted via a three-dimensional format, provides even more detail of the morphology of the skull (**Figure 78.2**). In addition, a CT scan allows evaluation of the intracranial contents. [**]

Raised intracranial pressure

It is logical to think of raised ICP developing as a result of failure of cranial expansion in the presence of continuing

Figure 78.1 Skull x-ray showing sclerosed suture. Arrow points to sclerosed metopic suture.

pressure from the growing brain. However, the relationship is complex, and other factors have been implicated. Raised ICP is not directly related to a decrease in intracranial volume,¹⁴ and venous hypertension has been identified as a result of a significantly narrower jugular foramen (6.5 mm versus 11.5 mm) in complex and syndromic patients with raised ICP.¹⁵

The reported incidence of raised ICP in patients with craniosynostosis shows wide variation, and there is variability in the threshold for diagnosis in reported studies, with values of 15 or 20 mm Hg chosen.¹⁶ Reported incidence in mixed cohorts of nonsyndromic and syndromic patients vary from 17 to 92 percent.^{14, 17, 18, 19} Studies that have compared the incidence of raised ICP in nonsyndromic and syndromic patients have shown a higher incidence in syndromic patients (approximately 50 percent) compared with nonsyndromic patients (approximately 25 percent).^{20, 21}

Diagnosis may be difficult because the classic clinical features of raised ICP are often absent. Thus, the child's development, in particular the acquisition of normal developmental milestones, vision, reading and language comprehension, motor skills, and general behaviour are important, and may require detailed specialist investigation, including ophthalmological assessment. Changes in visual-evoked potentials have been shown to be early indicators of raised ICP.^{22, 23}

Plain skull films may show the classic 'copper-beaten' appearance of chronically raised ICP (**Figure 78.3**) but

Figure 78.2 CT scan of patient with scaphocephaly. Note the absence of sagittal suture.

the absence of changes does not exclude raised ICP.²⁴ CT/magnetic resonance (MR) scan may be helpful but in cases where clinical assessment is equivocal, invasive ICP monitoring may be indicated, using either a traditional ICP bolt or, more recently, parenchymal fibre-optic transducers which have been shown to be reliable as recorders of ICP and are associated with a low rate of complications.²⁰

Transcranial Doppler ultrasonography has been proposed as an alternative noninvasive, inexpensive and safe alternative.²⁵ [*]

Hydrocephalus

Hydrocephalus is characterized by enlargement of the cerebral ventricles due to obstructed outflow of cerebrospinal fluid (CSF) somewhere along its path from the lateral ventricles, through the interventricular foramina, third ventricle, cerebral aqueduct, fourth ventricle and subarachnoid space to the sites of absorption. Hydrocephalus can occur in up to 20 percent of patients with craniosynostosis. It may be associated with chronic venous hypertension and hindbrain herniation, particularly in multisutural synostosis. The neurosurgical treatment of clinically significant hydrocephalus should be undertaken before more major craniofacial corrective surgery. [**/*]

Differential diagnosis

Not all abnormal head shapes are due to craniosynostosis, and accurate diagnosis is essential since the management of nonsynostotic head shape abnormalities is nonsurgical. The bones of the skull in early life are relatively soft and deformable, rendering the head susceptible to alteration in shape for a variety of reasons. Nonsynostotic causes of abnormal head shape include intrauterine and birth canal moulding, assisted delivery, e.g. Ventouse, intracranial abnormalities and post-natal deformational forces on the growing skull due to external pressure on the head or to

uneven muscle tension in the muscles attached to the skull base.

Intrauterine, birth canal and assisted delivery moulding will be present at birth but improve fairly quickly. Intracranial abnormalities will present at birth but persist. Post-natal deformational changes are not present at birth, develop gradually, and if the cause is removed, will improve. This is in contrast to craniosynostosis, which is usually apparent at birth and progresses with growth. Diagnosis is usually possible based on the history and examination alone, but confirmation of the patency of sutures can be confirmed by plain radiographs or CT scan if needed.

The most common presentation of nonsynostotic abnormalities of head shape is occipital plagiocephaly (for more detail see under Posterior skull deformity (including lambdoid synostosis)) due to habitual sleep position (the 'Back to sleep' campaign, encouraging parents to ensure babies sleep as far as possible on their backs, has contributed to this in recent years) or torticollis. Other causes include abnormal head posture due to vertebral abnormalities or ocular squint.

General principles of surgical management

The indications for surgery are treatment of raised ICP, correction of significant cosmetic deformity and prevention of future deformity by allowing normal growth to take place.

The general principles of surgery for the craniosynostoses are to remove the cause by excising the affected suture, correct the existing deformity by reshaping the affected area of the cranium and moving it into the position it would have been in had it grown normally. This leaves an expanded intracranial volume, with a space between the dura and the repositioned bone, into which the brain can expand, thus relieving raised ICP if present. It also corrects the cosmetic deformity. Leaving a gap in the region of the excised suture, which will mimic a normal suture, will allow future growth to take place by movement of the bone in response to continued brain growth.

Timing of surgery is important. Early surgery has the advantage that ICP is normalized without delay, and the deformity may be less severe since it has had less time to develop. However, early surgery may be followed by reossification at the site of the excised suture (restenosis), with a re-emergence of the condition requiring further surgery. The timing of surgery is, therefore, a balance between operating too early with the risk of restenosis and operating too late when there may be prolonged raised ICP, the deformity is greater and its correction may require more extensive surgery because of lack of future brain growth and, thus, capacity for skull remodelling in response to brain growth. Optimum timing is different for different sutures, and is discussed below under Timing of surgery.

Major craniofacial surgery carries significant risks and complications, and a dedicated team familiar with all aspects of the management of these patients is a prerequisite for surgery to be performed. This will include a dedicated ward and theatre with appropriately trained staff, a paediatric anaesthetist and HDU/PICU facilities. [**/*]

Single suture nonsyndromic craniosynostosis

SAGITTAL SYNOSTOSIS (SCAPHOCEPHALY)

This is the commonest isolated craniosynostosis, accounting for approximately 60 percent of nonsyndromic cases. It is far more common in males than females (4:1 ratio). The characteristic head shape is narrow transversely (due to lack of widening of the cranium perpendicular to the fused sagittal suture) and long anteroposteriorly (due to compensatory growth at the patent coronal and lambdoid sutures). The whole suture may be affected, with compensatory changes at the front and back, or the fusion may be predominantly anterior (with anterior compensatory growth resulting in frontal bossing) or posterior (with compensatory occipital bulging) (**Figure 78.4**).

The optimum age for operation is six to nine months, when suturectomy (midline linear strip craniectomy) with lateral osteotomies to permit brain growth ('lateral barrel staving') are performed. At this age, there is sufficient future brain growth to effect a continued gradual improvement, giving good results without the need for more extensive surgery, although some centres prefer a more complete operative correction when operating at an early age. In older patients in whom the diagnosis may have been delayed, more extensive procedures are necessary, and total calvarial remodelling may be needed.

Figure 78.4 Patient with scaphocephaly. The skull is long from front to back and narrow from side to side ('boat shaped').

ANTERIOR SYNOSTOSES

Coronal and metopic synostosis predominantly affect the forehead and supraorbital region, and surgical management is similar, irrespective of the involved suture.

CORONAL SYNOSTOSIS (FRONTAL PLAGIOCEPHALY AND BRACHYCEPHALY)

This is the second commonest simple craniosynostosis, accounting for approximately 30 percent of all cases. Coronal synostosis may be either unilateral or bilateral and can be associated with significant deformity of the facial skeleton, particularly in unilateral cases.

Unilateral (frontal plagiocephaly)

In unilateral cases there is flattening of the forehead on the ipsilateral side with a decrease in the anteroposterior dimension of the anterior cranial fossa and a resultant decrease in its volume. There are compensatory changes on the contralateral side with frontal bossing. Changes may affect the facial skeleton and result in significant complex facial asymmetry in more severe cases.

Bilateral (brachycephaly)

In bilateral cases there is a (usually) symmetrical reduction in anterior growth of the forehead, with compensatory widening of the skull, particularly in the temporal region. The forehead is recessed, there is poor brow projection and frontotemporal bossing may be present. The upper face is usually broad and there may be telecanthus or hypertelorism.

METOPIC SYNOSTOSIS (TRIGONOCEPHALY)

This represents approximately 10 percent of the total number of patients presenting with single suture craniosynostosis, although there is some early evidence from the experience of craniofacial centres that incidence of trigonocephaly may be on the increase. There is a deficiency of lateral growth of the frontal bones, with compensatory growth in the parietal and occipital regions, resulting in a widening of the back of the head. This, along with the narrow forehead, produces the characteristic triangularly shaped head (trigonocephaly). The fused metopic suture is often markedly elevated (ridged), further emphasizing the triangular shape. Owing to the reduction in lateral growth of the skull anteriorly, there is a decrease in the interorbital and intercanthal distances.

SURGERY

Fronto-orbital advancement and remodelling

Surgical correction of coronal and metopic synostosis is usually carried out between the ages of 12 and 15 months.

Earlier than this risks the need to repeat surgery because of restenosis, particularly if surgery is carried out before six months of age.²⁶

Surgery involves fronto-orbital advancement and remodelling (FOAR) described by Paul Tessier.²⁷ It is now the standard technique for expansion of the anterior fossa and correction of deformities involving the forehead and orbital rims. This involves removal of the frontal bone and supra orbital bone (supra orbital bar), remodelling and replacement in a forward position (**Figure 78.5**). This is usually carried out as a bilateral procedure, even in cases of unilateral coronal synostosis, since the deformity is never confined totally to the side of the fused suture, and results of bilateral surgery tend to be better than unilateral surgery in many cases.

Posterior skull deformity (including lambdoid synostosis)

Flattening of the occipital region is seen frequently and can happen for a variety of reasons, the most common of which is due to prolonged pressure on the occipital region during sleep, where the child is put to sleep on its back. The pressure causes deformation of the relatively soft occipital bones, resulting in deformational posterior plagiocephaly. The deformity is not present at birth, but develops gradually over the first few months of life. As the child gets older, gains head control and becomes more mobile, spending less time on its back, the cause is removed or lessened, and the condition often improves

Figure 78.5 Diagram of FOAR. The frontal bone and supraorbital bar are removed, reshaped and replaced in an anterior position (see Fronto-orbital advancement and remodelling).

spontaneously. However, the deformity may be rather marked, and in moderate or severe cases, may remain noticeable despite the tendency for improvement. Similarly, torticollis with an imbalance in the action of the sternocleidomastoid muscles on each side may result in similar changes. Physiotherapy will usually correct limitations in neck movement, removing the underlying cause and allowing some spontaneous improvement. Other conditions affecting head posture (e.g. ocular squint and hemivertebral abnormalities) may have similar effects.

True lambdoid synostosis may cause occipital flattening, but is the rarest of all the isolated craniosynostoses (approximately 1 percent). It is usually unilateral, but in 15 percent of cases is bilateral. There is still controversy regarding the true relationship of lambdoid synostosis and posterior plagiocephaly.

Diagnosis is dependent on the history (present at birth), examination (ridged suture and specific indicators, e.g. ear position) (**Figure 78.6**) and radiological investigations (plain film or CT) demonstrating a fused suture.

Surgery is rarely indicated for posterior skull deformity, even when synostosis is suspected. The deformity is rarely very noticeable once it is covered by hair and the risk of raised intracranial pressure is very low. Surgery may be undertaken in very severe deformity but full correction is not possible because the skull base deformity, which manifests as change in ear position, is not correctable, and the presence of the dural venous sinuses (torcula) limits the extent of safe bone removal for remodelling.

Recently, there has been increasing interest in the use of moulding helmets to treat posterior plagiocephaly, but there is a lack of good evidence with regard to efficacy,

© Hodder Arnold / Scott-Brown 7E

Figure 78.6 Differences between positional and true lambdoid synostosis. Positional moulding produces a parallelogram-shaped head and the ear moves anteriorly on the affected side. Unilambdoid synostosis produces a trapezoid-shaped head and the ear moves posteriorly towards the affected suture.

and properly designed scientific study is required to establish their place in the management of craniofacial patients.

Endoscopic treatment of craniosynostosis

Over the last few years, surgeons in America have been using endoscopic techniques to treat stenosed calvarial sutures. Purpose-built systems utilizing 4 mm 0° and 30° rigid endoscopes allow visualization of the subgaleal space and the undersurface of the skull when dissecting the dura. Such techniques allow strip craniectomies (but not remodelling) to be performed, with a significant reduction in blood loss and blood transfusion rates. To date, successful treatment of sagittal, metopic, lambdoid and coronal suture synostosis has been performed when such methods have been allied to the use of custom-made cranial orthotic moulding helmets. Further studies are required to establish the efficacy of this method of treatment. Successful treatment of isolated suture synostosis for 70 patients treated over a four-year period has been reported.²⁸

SYNDROMIC CRANIOSYNOSTOSIS

A syndrome is defined as a constellation of symptoms and signs that collectively characterize an abnormal condition or disease state. Syndromic craniosynostoses result from an interaction between genetic factors, molecular and cellular events, mechanical and deformational forces, and secondary effects of each of these on normal growth and development.

The clinical manifestation of some syndromes may vary from mild (unnoticeable) to severe.

Crouzon syndrome

Described in 1912 by a French neurosurgeon, this syndrome affects the face and cranium and occurs in 1:25,000 live births. Crouzon syndrome is characterized by craniosynostosis and maxillary hypoplasia with shallow orbits causing ocular proptosis. There is often bicoronal synostosis (brachycephaly) but occasionally the sagittal suture may also be affected. The main abnormality is an underdeveloped midface which results in prolapse of the globes ('exorbitism'), hypoplasia of the malar bones, retromaxillism and a resultant malocclusion. Anomalies of the middle ear and atresia of the external auditory canal may give rise to a conductive hearing loss. Abnormalities are usually confined to the craniofacial region although there may be systemic anomalies.⁴ Intelligence is usually normal. Crouzon syndrome is caused by mutations in FGFR2 and is autosomal dominant, although new mutations frequently arise.²⁹ The severity of this condition is extremely variable, even within the same family, and

therefore a mildly affected parent may only be diagnosed after the birth of a more severely affected child. Severity may vary from a barely noticeable degree of proptosis and midfacial hypoplasia to, more rarely, cloverleaf skull.

Apert syndrome

Described in 1906 by Apert, this syndrome has an incidence of 1:60,000 live births. There is an autosomal dominant pattern of inheritance although most cases of Apert syndrome occur without a family history as a result of new mutations and there is a link with advanced paternal age.³⁰ The main features of this condition include craniosynostosis, abnormal midfacial development and fusion of the digits of the hands and feet (syndactyly). Abnormalities of the midface and cranium are evident at birth with brachycephaly and midface retrusion causing an anterior open bite (malocclusion). Cleft soft palate or bifid uvula is present in 30 percent of cases. Fixation of the stapes footplate may cause a conductive hearing loss. There may be other associated malformations and intellectual ability may vary from normal to significantly impaired.³¹ Apert syndrome is caused by mutations in FGFR2; in two-thirds of cases the mutation is Ser252Trp, and is Pro253Arg in the remaining one-third.³²

Pfeiffer syndrome

First described in 1964, Pfeiffer syndrome is similar to Crouzon syndrome, and is characterized by craniosynostosis and midfacial hypoplasia with shallow orbits. However, additional features of Pfeiffer syndrome are broad thumbs and broad great toes. Severity of craniofacial anomalies can vary from mild midfacial hypoplasia to cloverleaf skull. Coronal sutures are most commonly affected with resultant brachycephaly. Other features may include skeletal anomalies such as fusion of the elbow joint, solid cartilaginous trachea and choanal stenosis. Three clinical subtypes have been suggested depending on the extent of associated features.⁴ Pfeiffer syndrome is caused by mutations in FRFR1 and FGFR2, in some cases the same mutations that can cause Crouzon syndrome. Inheritance is autosomal dominant although many cases arise as a result of new mutations. Intelligence varies from normal to mild learning difficulties, although central nervous system abnormalities may occur in severe cases.¹¹

FGFR3-associated coronal synostosis syndrome (Muenke craniosynostosis)

This increasingly recognized autosomal dominant condition is associated with unilateral or bilateral coronal synostosis and a variety of minor anomalies. The cause is a specific mutation of FGFR3, the Pro250Arg mutation.³³

The phenotype this causes is extremely variable, even within the same family, and includes coronal synostosis, macrocephaly without synostosis, ptosis and minor anomalies of the hands and feet. Intelligence is usually within normal limits although learning difficulties, usually mild, may be present. The effect of the mutation may be so mild in some family members that they are unaware of any craniofacial problems and could be offered gene testing to clarify their carrier status.

Saethre–Chotzen syndrome

This was first described in 1931. This is an extremely variable autosomal dominant condition, although abnormalities may be milder than in other syndromic craniosynostosis conditions. Owing to this, a mildly affected parent may not be aware that they also have the condition until after their more obviously affected child is diagnosed. The most commonly affected suture is the coronal suture and the craniofacial abnormalities are frequently asymmetric. Associated features may include ptosis, a low anterior hairline, small ears with a prominent horizontal crus, mild cutaneous syndactyly and broad thumbs and great toes. Mutations in the gene *TWIST* cause Saethre–Chotzen syndrome but the phenotype has also been seen in association with Pro250Arg mutations in *FGFR3*.³⁴

Craniofrontonasal syndrome

This condition is characterized by craniosynostosis which is usually coronal, frontonasal dysplasia, curly or frizzy hair, sloping shoulders and ridged nails. As part of the frontonasal dysplasia there is hypertelorism, a broad nasal bridge and, occasionally, a bifid nasal tip. There may also be skeletal anomalies such as joint hyperextensibility, scoliosis and broad toes. The inheritance is X-linked and, unusually for this form of inheritance, females are more severely affected than males. The gene *EFBN1* has recently been identified as causative.³⁵

Carpenter syndrome

This very rare autosomal recessive condition is characterized by craniosynostosis which may affect all sutures causing a cloverleaf skull, and also polysyndactyly (accessory digits with fusion of the digits) and brachydactyly (shortened digits). Mixed hearing loss may also occur. Patients may have obesity and may show learning difficulties.³⁶ The causative gene has been identified as *RAB23*.³⁷

Kleeblattschädel anomaly (clover leaf skull)

This describes a trilobar skull and is usually caused by pansynostosis involving the coronal, lambdoid and

metopic sutures, with bulging of the brain through open sagittal and sometimes squamosal sutures. The prognosis is often, but not universally, poor. Cloverleaf skull is a nonspecific anomaly and may be an isolated defect or part of wider syndromes. As such, the aetiology of cloverleaf skull is varied. It may be seen in patients with certain chromosomal abnormalities or be a feature of syndromes such as Pfeiffer, Apert, Crouzon and Carpenter.

Management

The aim of treatment in the craniofacial dysostosis group of patients is the same as for nonsyndromic craniosynostosis patients, which is to provide surgical correction for the abnormal shape (cosmetic) and restore volume (function).

Before treatment of the craniofacial anomaly, associated factors may need to be addressed. These include the compromised airway, globe protrusion, feeding and other medical abnormalities (heart, lung, etc.). Correction of craniosynostosis in infancy and midface retrusion in childhood are the mainstays of surgical treatment and require coordination with dentists, orthodontists, speech and language therapists and psychologists.

Airway

Respiratory problems may arise due to maxillary hypoplasia and, in some instances, tracheomalacia and choanal stenosis. Measures that may be useful include specific positioning of the patient, nasal stents, insertion of a nasopharyngeal airway and more complex strategies such as continuous positive airway pressure, endotracheal intubation or even tracheostomy. In the older child it may be necessary to perform adenoidectomy and/or tonsillectomy if indicated. This should be approached with caution where a cleft palate – often a submucous cleft – is present owing to potential creation or exacerbation of velopharyngeal insufficiency. Compromise of the airway may only be apparent when the child is asleep. Sleep studies may be required in some patients. Obstructive sleep apnoea is dealt with in more detail in Chapter 85, Obstructive sleep apnoea in childhood.

Visual complications

Owing to midfacial hypoplasia allied with temporal bulging, the orbits may be shallow and globe protrusion may happen. Most patients do not develop complications. Papilloedema, optic atrophy and progressive optic nerve dysfunction may accompany increased ICP even without evidence of hydrocephalus and even with open fontanelles. Uncorrected refractive error, strabismus, ptosis and corneal abrasion can lead to amblyopia, which if not reversed can lead to permanent visual disability. Proptosis due to the

inability to close the eyelids can lead to corneal abrasion. Craniosynostosis syndromes can be associated with missing extraocular muscles or muscles with abnormal insertions, resulting in ocular motility disorders.^{38, 39}

Emergency treatment is usually conservative with the use of protective eye chambers or tarsorrhaphy. Rarely, early forehead/midface advancement may be indicated where corneal protection is impossible. In the older child the cosmetic aspects of ocular problems will be addressed with fronto-orbital advancement and midface surgery.

Papilloedema, optic atrophy and progressive optic nerve dysfunction may accompany increased ICP.

Uncorrected refractive error, strabismus, ptosis and corneal abrasion can lead to amblyopia.

Feeding

In cases of midface hypoplasia there is the potential for maldevelopment of oropharyngeal function. Difficulties may include problems achieving lip seal (sucking may be impaired), airway reduction and the presence of cleft palate. This, in the short-term, will have an impact on swallowing and thus feeding and in the long-term, an influence on the development of speech and language. Assessment by speech and language therapists and nutritionists is thus very important. It may be necessary to insert a naso-gastric tube or, in some cases, provide a feeding gastrostomy.

Intracranial pressure

The incidence of raised ICP in the syndromic patient is approximately twice that of the nonsyndromic patient. Assessment and manifestations have already been covered in a previous section (see Single suture nonsyndromic craniosynostosis above). In cases where there is evidence of raised ICP in a patient who is less than the ideal age for fronto-orbital advancement (particularly in the presence of a posterior constriction), early posterior skull release should be considered as an initial procedure.²⁶ Posterior skull release involves a posterior craniotomy allowing a free segment or a segment fixed in new position allowing increased intracranial volume.

Definitive correction of syndromic craniosynostosis

This usually involves correcting the skull base and vault abnormality with FOAR early, in order to restore appearance and reduce the risk of development of raised ICP. Surgery to the midface is performed later; this restores appearance, enlarges the airway and improves the dental occlusion.

Timing of surgery

There is a balance between the risk of developing raised ICP if surgery is performed late and the risk of restenosis if surgery is performed early. Taking into account this balance, FOAR is usually performed at approximately 12–14 months age, as it is in nonsyndromic patients.

Timing of surgery to the midface is a matter of debate. Within the UK, surgery is usually delayed until the age of five to six years, or older, prior to the child starting secondary education. This delay is intended to allow growth of the child so that the weight increases, as does the circulating blood volume. Midface surgery often results in significant loss of blood volume with much of the haemorrhage not directly amenable to local control.

There are instances when surgery is performed early if there is risk to the eyes or there is an ongoing airway problem.

Surgical procedures

The type of surgery is dictated by the pattern of the deformity. There are three basic operations available.

1. The **Le Fort III** osteotomy involves advancement of all midfacial structures inferior to the frontal bone, i.e. nose, zygomas and maxilla en bloc. This requires a bicoronal flap for access to the nasal root, orbits and zygomatic bones and osteotomies of the nasal root, medial orbital walls, orbital floor, lateral orbital wall, frontozygomatic suture and pterygomaxillary complex. This allows mobilization of the midface. Internal fixation and bone grafts ensure satisfactory healing and stability.
2. Where midface hypoplasia is associated with hypertelorism, a **facial bipartition** may be carried out. It essentially involves a Le Fort III osteotomy to advance the midface and excision of a V-shaped segment of bone from the midline, creating two independent hemifacial segments, which can then be brought together to reduce the interorbital distance.
3. **Monobloc** procedure involves advancement of the forehead and midface at the same time by combining a Le Fort III procedure with FOAR.

Distraction osteogenesis

Conventional surgery involves osteotomy, mobilization and bone movement at one operation. Bone grafting and internal fixation are required to ensure healing and stability. It has the advantage of completing treatment at one operation. However, where the required bone movement is large (greater than 10 mm in the midface) or there is significant scarring of surrounding soft tissues, the

desired movement may be difficult or impossible to achieve. The alternative of distraction osteogenesis can overcome these difficulties. Distraction osteogenesis involves initial osteotomy without mobilization and application of an internal or external distraction device, which is activated after a one-week latent period and produces a movement of 1 mm per day. This allows gradual adaptation of a surrounding soft tissue envelope, as well as osteogenesis within the osteotomy gap, allowing for greater movements without the need for bone grafting or internal fixation. Once the desired movement has been achieved, the distractors are left *in situ* for a further eight weeks to allow consolidation of the newly formed bone. Distraction therefore has the advantage of being able to produce larger movements without the requirement for bone grafts or internal fixation. The disadvantages are that the treatment is prolonged, the patient has to tolerate the distraction devices and a second operation is often required for distractor removal. In most craniofacial patients, the advantages of distraction outweigh the disadvantages compared with conventional surgery and, therefore, the majority of midface advancements are now carried out using distraction (see **Figure 78.7**). [***/**/*]

Complications of surgery

Craniofacial surgery carries significant risks. Intubation may be difficult because of abnormal anatomy, there may be coincident systemic abnormalities and the operation may be prolonged.

Complications vary with the extent of the surgery. In the literature, death is reported in 1.5–2 percent of cases as a result of uncontrolled haemorrhage, meningitis, respiratory obstruction or cerebral oedema. The major complications of surgery will be addressed in turn.

BLOOD LOSS

The patient has a small absolute blood volume and there may be appreciable sudden haemorrhage, in particular from the cerebral sinuses. Blood loss varies with the timing and extent of the surgery. In a simple suture release, blood loss is in the region of 100 mL. Blood transfusion is commonplace for infants undergoing this surgery and for older children having more extensive procedures. Risk of viral transmission is low but the consequences are potentially devastating. Avoiding

Figure 78.7 Patient with Crouzon syndrome treated with midface distraction. Previously having undergone FOAR at 15 months, now undergoing midface distraction (Le Fort III) at the age of nine years with rigid external distractor (RED frame). The end position is a midface that has been advanced and brought inferiorly.

transfusion is not always possible but providing the intravascular volume is maintained then patients can tolerate low haemoglobin levels.^{40, 41}

AIR EMBOLISM

A major danger in craniofacial surgery is ingress and embolization of air through the circulation. This can occur at any stage during surgery, from inserting large-calibre central lines, raising a scalp flap or opening into the major sinuses. In anticipation of blood loss and air embolization, an arterial and central venous line are routinely used along with a number of peripheral lines. A significant air embolism will result in hypotension, bradycardia and cardiac arrest.

CEREBRAL OEDEMA

All measures should be taken to avoid cerebral oedema. Positioning the patient correctly, ensuring correct endotracheal tube positioning and maintaining the correct intravascular fluid replacement are all vital. There should be minimal brain retraction and handling, particularly in cases of pre-existing raised intracranial pressure as this predisposes the patient to a developing cerebral oedema. In many cases the use of systemic steroids (e.g. dexamethasone) may be useful in minimizing cerebral oedema.

DURAL TEAR

Craniofacial surgery such as suturectomy and vault expansion are essentially extra dural procedures. In certain circumstances, for example repeat surgery or when 'copper beating' of the inner table of the skull is present, it may be impossible to avoid tears of the dura mater.

CEREBROSPINAL FLUID FISTULA

Cerebrospinal fluid leak is uncommon but will take place if a dural tear is not either recognized or adequately repaired. CSF can then leak through the scalp wound or, perhaps more commonly, leak into the nose and present as CSF rhinorrhoea. Often this is transient, lasting a few days and sealing spontaneously. Obvious fistulae that fail to resolve must be treated. Of more concern are those that persist unnoticed and lead to infection at some later date.

INFECTION

Infection can occur, particularly in cases involving communication with the paranasal sinuses, and result in meningitis, intracerebral abscess or subdural empyema. Chronic infection can also manifest as lost bone graft or

implants. Treatment of postoperative infection is aggressive but conservative, systemic antibiotics and local debridement but with preservation of bone flaps at all costs.

INTRACEREBRAL/SUBDURAL HAEMATOMA

Haematoma can present in the early postoperative phase with unexpected signs of raised intracranial pressure or 'lateralizing' signs.

BLINDNESS

Surgery around the optic apex and skull base has the potential to damage the optic nerves or tracts. In particular, hypertelorism procedures and monobloc midfacial advancement carry a risk to these structures.

RESTENOSIS

The aim of much cranial vault surgery is to release the prematurely fused sutures, thereby allowing unimpeded brain growth. The gaps created gradually reossify. Occasionally, restenosis takes place, and with continued brain growth there is a rise in intracranial pressure. This tends to happen more commonly in syndromic craniosynostosis than in nonsyndromic cases.

The potential for reossification declines with increasing age of the child. In children over one year of age large bony defects of the skull vault may not close entirely. In some cases it is necessary to repair these defects using a split calvarial bone switch procedure.

Outcome of surgery for craniosynostosis

Measurement of the outcome of craniofacial surgery is difficult and multifaceted. Assessment of the aesthetic result is subjective and surgeons, parents, families and patients may have different perspectives. The various forms of craniosynostosis are heterogenous and even within a single diagnostic category severity is variable. This includes both the skull and facial components of the deformity.²⁶ A generally accepted, simple and limited outcome measure is the reoperation rate; Whittaker *et al.*⁴² have devised a four-point scale to describe this (see **Table 78.3**). Most of the published follow-up studies, not surprisingly, report a better outcome for single suture compared with multisuture involvement and for nonsyndromic compared with syndromic patients. Major secondary procedures were required in 37 percent of syndromic⁴³ compared with 13 percent of nonsyndromic patients,⁴⁴ while other authors reported reoperation rates of 17 percent for syndromic and 5 percent for nonsyndromic patients.²⁶

Table 78.3 Whittaker classification.

Category	Classification
I	No refinements or surgical revisions considered advisable or necessary
II	Soft tissue or lesser bone contouring revisions advisable; can be carried out on an outpatient basis or minimum two-day hospitalization
III	Major alternative osteotomies or bone graft repositioning, onlay bone grafts, Le Fort advancement; these procedures are not as extensive as the original operations
IV	A major craniofacial procedure is advisable, duplicating or exceeding the original procedure

HEMIFACIAL MICROSOMIA

Hemifacial microsomia is part of a spectrum of conditions which also includes Goldenhar syndrome (the oculoauriculovertebral spectrum). It results from a failure of the normal development of structures derived from the first and second branchial arches, and affects bone, soft tissues, muscles and nerves. It is the second most common congenital facial anomaly, next only to cleft lip and palate, with a reported incidence of 1:5000 births. It is usually unilateral but can occur bilaterally in 10 percent of cases,⁴⁵ although usually asymmetrically (see Chapter 65, Head and neck embryology and Chapter 77, Cleft lip and palate).

Aetiology

Although most cases occur sporadically, multiple cases in families have been reported. It is one of several structural anomalies that are postulated to result from vascular disruption. Other investigators have found a relationship between disturbed neural crest migration and defects of the first and second branchial arches (this seems possible, especially in view of the frequency of associated cardiac anomalies). Risk of hemifacial microsomia is increased with multiple pregnancies, second trimester vaginal bleeding, heavy alcohol intake, diabetes and drugs (e.g. thalidomide and retinoic acid).

Classification

A number of classification systems exist. The OMENS classification is based on the anatomical structures affected, OMENS being an acronym for orbit, mandible, ear, nerves and soft tissue. A score is allocated to each anatomical area depending on the extent of the deformity.⁴⁶ Pruzansky classified hemifacial microsomia based on mandibular morphology, grade I being the mildest form and grade III the most severe (see **Tables 78.4** and **78.5**).^{47, 48}

Table 78.4 OMENS classification of hemifacial microsomia.

	Category	Grade (0–3)
O	Orbit	
M	Mandible	
E	Ear	
N	Nerve	
S	Soft tissue	

0, no abnormality; 3, severe abnormality.

Table 78.5 Pruzansky classification of hemifacial microsomia.

Type	Classification
I	Miniature mandible and temporomandibular joint (TMJ), all structures present but hypoplastic
II ^a	Small abnormally shaped mandibular ramus and underdeveloped displaced TMJ
III	Absence of mandibular ramus and glenoid fossa

^aGroup II subsequently subdivided by Kaban as follows: type IIa, glenoid fossa in acceptable position, no TMJ reconstruction required; type IIb, TMJ in abnormal form and location, TMJ and ramus reconstruction required.

Clinical diagnosis

Clinical manifestations are variable. Based on the OMENS classification there may be subtle orbital asymmetry, mandibular asymmetry with hypoplasia on the affected side leading to an eccentric chin point and dental malocclusion (see **Figure 78.8**). Ear deformity occurs in up to 95 percent⁴⁹ and includes microtia in approximately half of patients. Associated hearing loss depends upon the development of the external auditory meatus and the middle ear. Hypoplasia of the middle ear with fusion or absence of the ossicles may occur. Neuromuscular deficiencies involve the trigeminal and facial nerves, with hypoplasia or absence of masticatory muscles and/or muscles of facial expression. There is facial weakness in approximately 12 percent of patients⁵⁰ and, more rarely, other cranial nerves may be involved.

© Hodder Arnold / Scott-Brown 7E

Figure 78.8 Hemifacial microsomia. Patient's mandible has been advanced anterosuperiorly with the aid of an external distractor following a sagittal split osteotomy.

Soft tissue asymmetries are partly related to hypoplasia of the masticatory and facial muscles, but other tissues such as salivary glands may be absent.

Goldenhar syndrome (oculoauriculovertebral spectrum) is a variant of hemifacial microsomia which includes epibulbar dermoids and occasionally cervical and rib anomalies, cardiac defects and renal anomalies (see Chapter 80, Facial paralysis in childhood).

Management

Management is varied and depends upon the severity of the condition, tissues involved and the resulting functional and aesthetic defects. Multidisciplinary team management is essential, and includes assessment,

monitoring and management of airway difficulties, including sleep apnoea, hearing and speech and language development.

Correction of the underlying bony and soft tissue deficits usually involves staged treatment, often with multiple procedures, given the diversity and complexity of the underlying defects.

The timing and technique for correction of mandibular deficiency is dependent upon the severity of the deformity. Mild (grade I) deformity can be managed in late adolescence with standard orthognathic surgery in combination with orthodontic treatment. In the more severe asymmetries, there may be an advantage in surgical correction earlier in childhood. Deficient growth of the affected side of the mandible may constrain maxillary and midfacial development, and early correction may allow better development in these areas. Early operation, therefore, has the advantage of minimizing subsequent deformity. However, growth of the affected side of the mandible is still likely to be deficient, and if early treatment is undertaken there is often a need for a repeat correction in later childhood and adolescence. If treatment is delayed until growth has finished, then surgical correction later may involve a more extensive procedure to correct the maxillary and midface asymmetry. Early correction of mandibular deformity is usually carried out utilizing distraction osteogenesis rather than conventional surgery with bone grafting, and in types IIa and IIb mandibular deformity where sufficient bone exists to allow this to occur, distraction is an option. In severe (type III) cases, there may be insufficient bone for osteotomy. In these patients costochondral grafting introduces new bone into the ascending ramus, and the inclusion of costochondral junction and a small cap of costal cartilage replaces the missing condylar growth centre, with the prospect of future growth of the costochondral graft. Growth of costochondral grafts is at best unpredictable and long-term outcomes have been variable using this technique; one study has shown growth of the grafted side as unequal (42 percent) or poor (16 percent) as compared with the normal side. Other procedures which may be of benefit include ear reconstruction, facial reanimation and soft tissue augmentation utilizing a variety of techniques.[**/*]

TREACHER COLLINS SYNDROME (MANDIBULOFACIAL DYSOSTOSIS)

Treacher Collins syndrome (otherwise known as mandibulofacial dysostosis) is characterized by the absence or hypoplasia of the zygomatic bones, eyelid abnormalities and mandibular hypoplasia, (see Chapter 75, Management of congenital deformities of the external and middle ear).

Aetiology

Unlike hemifacial microsomia, this is an autosomal dominant condition, although approximately 50 percent of cases have no family history and therefore represent new mutations. Its incidence is approximately 1:50,000 live births.⁵¹ Severity is very variable and other family members may be very mildly affected. Intelligence is usually normal. Treacher Collins syndrome is caused by mutations in the gene *TCOF1*.⁵²

Clinical manifestations

The palpebral fissures may be down-slanting, with colobomas of the lower eyelid and eyelash/follicle malformations being common. A hypoplastic midface with poorly developed or absent zygomas, associated with mandibular hypoplasia results in a very characteristic facial appearance (**Figure 78.9**). Features are bilateral and often symmetrical. Bilateral ear abnormalities including hypoplasia, microtia or anotia, hypoplasia or atresia of the external auditory meatus, middle ear anomalies and associated hearing defects are common. There is cleft palate in 35 percent of cases.

Management

Management of the airway in the neonate is required to overcome respiratory obstruction associated with mandibular hypoplasia or choanal atresia. Early feeding difficulties may also need to be addressed. Further management may include repair of cleft palate, provision of bone conducting hearing aid followed by a bone anchored hearing aid, and close monitoring and

intervention for speech and language development. Eyelid abnormalities may need surgical correction, hypoplastic or absent zygomas may be reconstructed, usually using calvarial bone grafts, and mandibular deficiency can be corrected with conventional osteotomy or distraction osteogenesis. [**/*]

ENCEPHALOMENINGOCOELE

Encephalomeningocoele represents a herniation of meninges with or without associated brain tissue, through a bony defect of the calvarium. They are a congenital anomaly representing one end of the spectrum of neural tube defects. Its diagnosis is based on the finding of either meninges and CSF (meningocoele) or nervous tissue (encephalocoele) beyond the confines of the calvarium.

The incidence of encephalocoele is reported to be as high as 1:3000 live births in South-East Asia and as low as 1:10,000 live births in North America.⁵³

Aetiology

Encephalocoeles may be isolated or associated with other anomalies. When other problems coexist, causes include chromosomal abnormalities, single gene disorders, teratogens and disruptions such as amniotic bands. The primary abnormality in the development of an encephalocoele is a mesodermal defect that develops when the surface ectoderm fails to separate from the neuroectoderm. This results in a defect in the calvarium and dura. Within the calvarium itself there may be failure of bone formation or pressure erosion from expanding intracranial contents. The aetiology of isolated cases is thought to be multifactorial, with both genetic and environmental

© Hodder Arnold / Scott-Brown 7E

Figure 78.9 Treacher Collins. Abnormalities of zygomatic bones, ears, eyelids and mandible. Note tracheostomy.

factors playing a part. The widespread use of folic acid prior to conception and during pregnancy aims to reduce the frequency of neural tube defects in the general population. After the birth of an affected child, the use of high-dose folic acid prior to and after conception is recommended for subsequent pregnancies.⁵⁴

Diagnosis

Detailed imaging is required for any nasal mass in the neonate prior to biopsy since anterior encephalocoeles may be confused with dermoids, neurofibromas and teratomas. Investigations may include an MR scan demonstrating a mass with intracranial connection and a CT scan demonstrating a bony defect in the calvarium (see **Figure 78.10** and Chapter 82, Nasal obstruction in children).

Classification

There are various classification systems for encephalocoele, based on the contents of the sac, site of the swelling, location of the skull defect and whether the swelling is overt or occult. The most commonly applied system is that relating to the location of the cranial defect. Encephalocoele may be **occipital**, **frontoethmoidal**, **parietal** or **sphenoidal**. Whereas occipital sites are most common in Europe, frontoethmoidal encephalocoeles are most common in Asia.

Management

Indications for treatment are the presence of a CSF leak or high probability of a CSF leak. Functional issues include patency of airway, allowance of normal feeding and

unobstructed vision. In cases where the encephalocoele is large and visible there may be cosmetic issues.

There is an indication for early treatment when a CSF leak is present, otherwise surgery may be deferred until the child is older. This extra time allows the child to grow and further investigations, i.e. imaging, to be performed.

Technique

Principles of treatment involve excision of the hernial sac/reduction of contents, dural repair, bony repair and correction of any associated secondary deformity. Secondary deformity may include hypertelorism, orbital dystopia and destruction of the nasal bridge (in cases of anterior encephalocoeles).

Outcome

The prognosis is dependent upon the contents, site and size of the defect. Some encephalocoeles are incompatible with survival. Approximately three-quarters of the patients with encephalomeningocoele who survive will have a long-term mental deficit, and the best overall prognostic factor is the absence of brain tissue within the herniated sac. Outcome for treated anterior encephalocoeles tends to be better than occipital encephalocoeles, with figures as low as four of 65 with long-term intellectual impairment.⁵³ [**/*]

CRANIOFACIAL CLEFTS

A craniofacial cleft happens as a result of a failure of fusion of the various embryonic processes from which the craniofacial complex is formed. The exact incidence of craniofacial clefts is not known but can be estimated to be approximately 2:100,000 live births.⁵⁵

Aetiology

The interplay of hereditary and environmental factors is complex and with few total cases is yet to be elucidated in detail. The majority of craniofacial clefts occur sporadically. Many factors have been implicated in the formation of craniofacial clefts, including drugs, e.g. anti-convulsants, corticosteroids and chemotherapeutic agents, radiation, infection, amniotic bands and metabolic disturbances during pregnancy. Craniofacial clefts may also be seen as part of wider syndromes such as Goldenhar syndrome.

Figure 78.10 CT scan of encephalocoele. Note deficiencies of cranium.

Classification

Tessier⁵⁶ classified facial clefts according to their relationship with the orbit, nose and mouth. Numbering the clefts from 0 to 14 allowed the lower numbers to relate to the facial clefts and the higher numbers the cranial extensions (See Chapter 77, Cleft lip and palate).

Clinical features

The clinical features are variable depending on the type of cleft. Clefts affecting the interorbital area result in hypertelorism and orbital dystopia (see Figure 78.11).

Management

Surgical treatment will depend upon the site, size and severity of the cleft. The extent of the cleft can be variable, ranging from a notch in the soft tissues or soft tissue deficiency, or may be severe affecting skin, bone and brain.

Treatment will usually involve reconstitution of the layers, replacement of missing anatomical structures and normalization of secondary distortions. [**/*]

Frontonasal dysplasia

Frontonasal malformation, or frontonasal dysplasia, is characterized by wide spacing of the eyes (hypertelorism), a characteristic hairline ('widow's peak'), a broad nasal bridge and bifid nasal tip. Occasionally, there may be midline clefting of the skull or palate. Most cases are sporadic and aetiology is unclear.

Figure 78.11 Facial cleft. Preoperative and postoperative views (see under Craniofacial clefts above).

KEY POINTS

- The term 'craniofacial anomalies' encompasses a large number of different conditions.
- For many conditions, monitoring and intervention is required from birth to maturity and often well into adult life.
- Many children with craniofacial anomalies have associated (noncraniofacial) anomalies and complex medical and surgical conditions.
- The systemic consequences of localized functional impairment require the expertise of a wide variety of specialists.
- Optimum management of paediatric craniofacial anomalies demands all the facilities and expertise available in a modern dedicated paediatric setting.

Best clinical practice

- ✓ The neurosurgical treatment of clinically significant hydrocephalus should be undertaken before more major craniofacial corrective surgery. [Grade C]
- ✓ Major transcranial and facial procedures carry significant risks and complications. These must be discussed in detail with patients and families before surgery is undertaken. This is best achieved in specific multidisciplinary preoperative clinics and involves not only the perioperative risks but also the long-term functional and psychological consequences of such complex procedures. [Grade D]
- ✓ Tonsillectomy with or without adenoidectomy should be approached with particular caution in children with craniofacial anomalies. A cleft palate – often a submucous cleft – may be present. Adenoidectomy may be best avoided but if required consider limited surgery under direct vision to reduce the risk of velopharyngeal insufficiency. [Grade D]
- ✓ Detailed imaging is required for any nasal mass in the neonate prior to biopsy. Anterior encephalocoeles may be confused with dermoids, neurofibromas and teratomas. Investigations may include an MR scan demonstrating a mass with intracranial connection and a CT scan demonstrating a bony defect in the calvarium. [Grade C]
- ✓ Prenatal diagnosis by genetic analysis of chorionic villus sample or amniotic fluid is available for some conditions in which the causative genetic abnormality is known. [Grade B]
- ✓ Prenatal ultrasound scanning later in pregnancy may reveal abnormal craniofacial contour or associated skeletal or systemic abnormalities in syndromic conditions. [Grade C]

Deficiencies in current knowledge and areas for future research

- The aetiology of craniosynostosis is still not understood. The complex interactions between the environment, genetic factors and other unknown stimuli are yet to be elicited.
- The role of moulding helmets and the possibility of more widespread use of endoscopic techniques for the treatment of craniosynostosis is yet to be confirmed.
- The best timing for many of the surgical procedures performed for many of the craniofacial anomalies is still uncertain and is a matter for debate and future research.

SEARCH STRATEGY

A number of search strategies were employed for this chapter. Using dizziness, vertigo, paediatric/pediatric/child and the major conditions as key words the following databases were consulted: Embase, Ovid Medline (R) and Journals @ Ovid full text subset.

INTRODUCTION

Children do not usually complain of vertigo; history and diagnosis can be elusive. Owing to this, the pattern of symptoms in the very young has a wide differential diagnosis. Once middle ear disease and congenital or hereditary sensorineural conditions have been excluded, a large percentage will have dizziness associated with migraine. Posterior fossa neurological disease should be considered; in older children, adult causes of vertigo may be seen. Reassurance that the prognosis is favourable, and antihistamines such as cinnarizine or, if appropriate, antimigraine treatments are usually effective.

MATURATION OF THE VESTIBULAR SYSTEM

The otic capsule develops early in gestation between the 4th and 12th weeks of intrauterine life. As the vestibular system is phylogenetically older than its auditory counterpart, each stage in development is in advance of the auditory system, and therefore less vulnerable to

environmental insult. The semicircular canals have formed from the utricular portion of the otic vesicle by the 30-mm stage, while the cochlear duct has two and a half coils by the 50-mm stage.¹ The vestibular nerve myelinates by 16 weeks *in utero*. By 24 weeks there is even a primitive vestibulo-ocular reflex present. After birth, at four months of age, the baby can tilt its head to keep it vertical. Bithermal caloric responses can be made in nine-month-old babies if necessary, to measure the vestibulo-ocular reflex. Vestibular nystagmus in children, however, tends to be of a lower frequency and greater amplitude. Maximum slow phase velocity readings are often similar to those in adults, but the normal range for the canal paresis and directional preponderance calculations are wider than that seen in adults. Congenital nystagmus resultant from macular visual loss differs however. [***]

Infantile reflex responses and motor milestones

The Moro response comprises a sudden bilateral extension of the upper limbs evoked by sudden jarring of the

cot or dropping the head backwards by a few centimetres. This response is present in normal children at birth, and disappears by the sixth month. The secondary inherent responses are righting responses and protective reactions. From four months, the infant will tilt the head to maintain it vertical if the trunk is tilted through 30°. The ages of sitting unsupported, crawling and walking, bear some relation to vestibular function but also depend upon neurodevelopment. Vision also plays an important part in postural control.

ASSESSMENT OF THE DIZZY CHILD

Symptoms of vertigo in children

Childhood vertigo results from a mismatch of information from the three different sensory systems: vestibular, visual and proprioceptive. Vertigo, however, is much more difficult to recognize in babies and children than in adults; children are not able to describe what they are experiencing and may present with other somatic symptoms such as cowering in the corner of the cot, falling to the ground crying, burying their head in their hands and vomiting. Interestingly, children born with a congenital lack of normal vestibular function often have no balance disturbance at all. Vision remains by far the most important sense for locomotor and balance acquisition.

It is helpful to direct the history taking with a number of principal and most likely diagnoses in mind. In the

paediatric age group the principal conditions to consider are:

- benign paroxysmal vertigo of childhood;
- basilar migraine;
- epilepsy;
- central causes of ataxia and loss of balance;
- vestibular neuronitis;
- BPPV;
- adult causes, e.g. Menière’s disease.

A more complete list appears in Table 79.1.

The presentation of vertigo varies quite dramatically according to the age of the child. While it is possible for two year olds to experience acute vertigo, young children cannot describe this, and may even present with torticollis. If there is a delay in motor milestones, children may present with poor balance or falling; this can also be associated with simple conditions such as ‘glue ear’. By five years of age, short-lived dizzy episodes can be described, the common cause being benign paroxysmal vertigo (BPV) of childhood. By the teenage years, migrainous vertigo, psychogenic vertigo and the adult vertiginous conditions are much more common.

History taking

It is helpful to establish the nature of the dizziness, whether it is true vertigo, loss of balance or a light-headed faint feeling. The duration and periodicity can be useful guides as may precipitating factors such as head or neck injury.

Table 79.1 Causes of childhood vestibular symptoms.

Conditions with hearing loss	Conditions with normal hearing
OME	Motion sickness
Suppurative ear disease	BPV of childhood
Cholesteatoma with fistula	Basilar migraine
Temporal bone trauma	Seizure disorders
Barotraumatic perilymph fistula	BPPV
Menière’s disease	Post-traumatic vertigo
Post-traumatic vertigo	Viral labyrinthitis or neuronitis
Enlarged vestibular aqueduct syndrome	Posterior fossa tumours
Other congenital temporal bone anomalies, e.g. CHARGE association	Cardiac causes: syncope and arrhythmias
Dehiscent superior semicircular canal syndrome	Acute poisoning
Drug-induced ototoxicity	Multiple sclerosis and Lyme disease
Congenital syphilis	CNS infections: Coxsackie A and B, echovirus encephalitis or HIV infection
Herpes zoster oticus	Meningitis: viral or bacterial
Congenital CMV infection	Chiari malformations
Metabolic conditions: Hurler’s syndrome, hypothyroidism	Hereditary cerebellar ataxias
Usher’s syndrome	Acute cerebellar ataxia

The presence of frequent headaches and whether they occur with vertigo or at other times is important. Associated vomiting may be an indication of an acute true vertigo, a migraine phenomenon or the presence of raised intracranial pressure. Associated hearing loss, otalgia or otorrhoea are important. It can be helpful to categorize childhood dizziness into conditions with normal hearing and those with associated deafness (Table 79.1).

A neurological history is helpful, specifically if there is anything to suggest temporal lobe seizures, visual or olfactory hallucinations. The developmental history, in terms of the motor milestones, or any regression should be ascertained. The presence of a recent pyrexial illness, the drug history both current, past and, indeed, *in utero* can be important, and various sorts of poisoning should be borne in mind in the child who becomes acutely ill with vertigo and may have ingested something while playing. In the ill febrile child a range of serious infectious diseases should be considered. In a slightly older child, it may be more apparent that the problem is one of fainting or hyperventilation, or that there are cyanotic attacks or palpitations in association with the dizziness.

The family history is relevant, especially one of maternal migraine, familial sensorineural deafness or neurofibromatosis type 2 (NF2).

Examination of the dizzy child

The routine paediatric examination will include otoscopy. Facial nerve function, tongue movements and the gag reflex should be checked. It is important to look at eye movements and, in particular, to search for nystagmus, which can be unmasked with the use of Frenzel glasses. The standard clinical balance assessments can be undertaken, for example Romberg's test, Unterberger's stepping test and the tandem heel-toe gait. It is helpful to make this fun for the child by introducing games, such as hopping and kicking a football, to assess balance function better. Optokinetic nystagmus may be viewed by watching a rotating drum, and a marked directional preponderance may be diagnosed. Dix-Hallpike positional testing should also be undertaken (see Chapter 240b, Evaluation of balance).

Cerebellar ataxia is seen on heel-toe tandem gait with dysmetria, but with normal ranges of lower limb motion and unchanged gait velocity and stride length. Characteristically, gait is wide based with dyssynergia and dysrhythmia, and balance is poor.²

Investigations

Audiometry is mandatory. This should comprise a pure tone audiogram or alternative threshold assessment, such as visual reinforcement audiometry, if the child's age or

development demands it. Objective testing with brain-stem auditory-evoked responses may be indicated. Tympanometry should also be undertaken.

Routine blood tests to exclude anaemia or other blood dyscrasias are worthwhile. The white cell count and inflammatory markers (erythrocyte sedimentation rate or C-reactive protein) may give a clue to an infective condition which could have led, for example, to cerebellar encephalitis. Serology should exclude congenital syphilis, and human immunodeficiency virus (HIV) disease might be considered.

Depending on the history and the level of concern, other investigations might include formal bithermal caloric testing with video-nystagmography or electronystagmography recordings.

Imaging the head and inner ears with magnetic resonance (MR) scanning and/or a high resolution computed tomography (CT) scan for the bony labyrinth and temporal bones will be indicated in selected children. For example, reassurance that there is no space-occupying lesion in a child with headaches and vertebrobasilar migraine or defining an enlarged vestibular aqueduct in association with sensorineural hearing loss could be important. If the diagnosis is clinically obvious however, then it is unnecessary to undertake brain scanning.

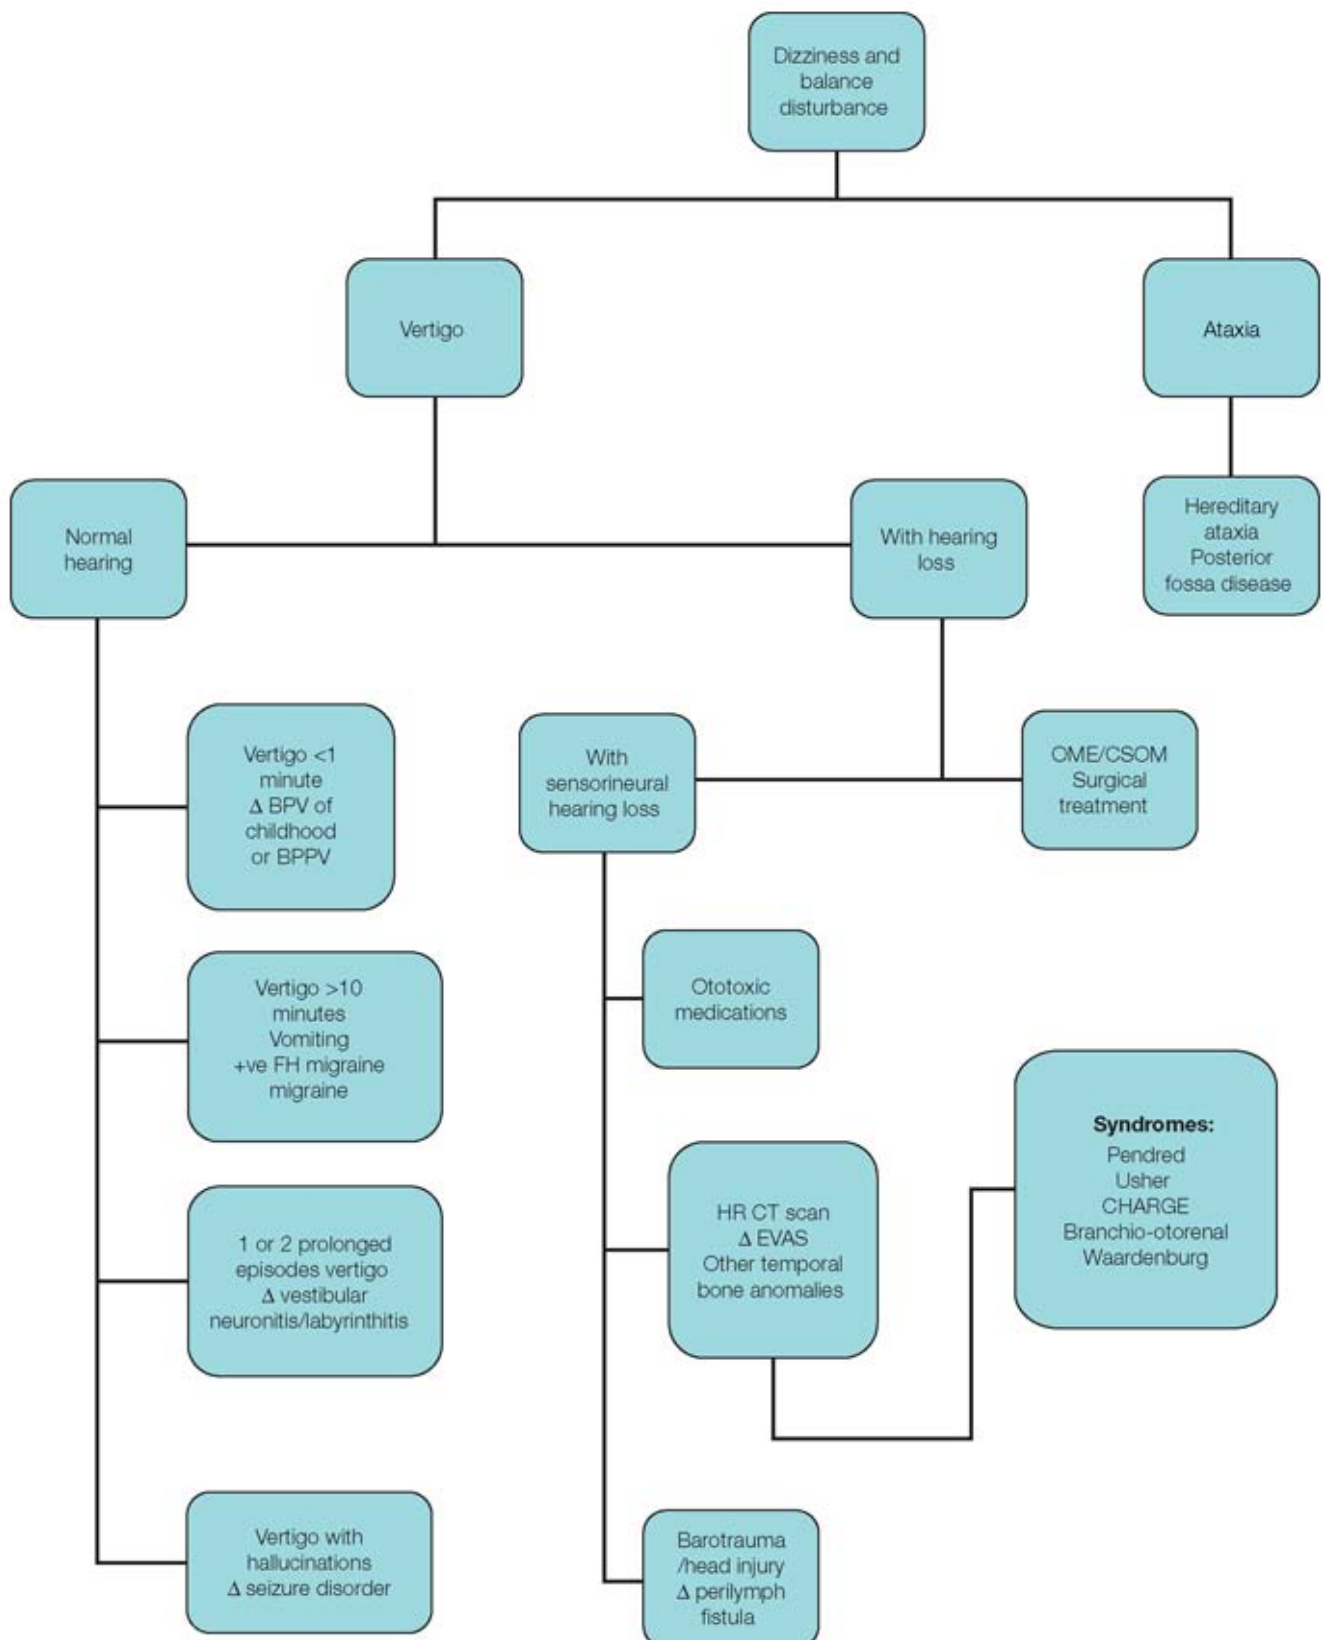

Where the history indicates it, referral for an electroencephalogram (EEG) and neurological opinion or for an electrocardiogram and cardiac review may have to be considered. [*]

CAUSES OF CHILDHOOD VESTIBULAR SYMPTOMS

The diagnostic flow chart (Figure 79.1) summarizes the diagnostic process in managing the child with vestibular symptoms. The conditions are discussed in more detail below.

VESTIBULAR CONDITIONS WITH NORMAL HEARING

Table 79.1 lists most of the conditions that can present with childhood vertigo, dizziness or balance problems. Although the differential diagnosis is extensive, in over half the children who present to the paediatric otolaryngologist with dizziness or disequilibrium, the cause will be otitis media with effusion (OME or 'glue ear'), BPV of childhood or dizziness as a migraine phenomenon.³ A further study indicates the most common causes for vertigo in children to be migraine in 31 percent and BPV of childhood in 25 percent.⁴ Other less frequent causes include trauma with deafness, delayed endolymphatic hydrops, benign positional vertigo and, more rarely, cerebellopontine angle tumour, seizures, acute vestibular neuritis or juvenile rheumatoid arthritis. In this study,

© Hodder Arnold / Scott-Brown 7E

Figure 79.1 Diagnostic flow chart for balance disturbances in children.

abnormalities were found in hearing in 24 percent, in positional testing in 5 percent, in 11 percent of bithermal caloric tests, and in 65 percent on rotational chair testing.⁴

Motion sickness

Motion sickness is caused by a conflict in the kinetic input, often with an excessive vestibular stimulation. Girls are more commonly affected than boys and it tends to settle at puberty. Interestingly, motion sickness can occur in people with blindness, but can also be caused by purely visual stimulation. There is an association with migraine and vestibular dysfunction.⁵

Benign paroxysmal vertigo of childhood

Benign paroxysmal vertigo of childhood is not a positional vertigo and is quite different from benign paroxysmal positional vertigo (BPPV). It occurs in children who are aged four or over, with no obvious precipitating factors. It is a very frequent cause of paediatric dizziness, being found in 35 percent of children with dizziness in one series.⁶ The child experiences short-lived acute vertigo for 30–60 seconds. He or she may fall or hold onto something suddenly and cry, becoming pale and sweaty. There is then a rapid return to complete normality a few minutes later. Nystagmus is present during attacks which are recurrent and variable in frequency. They can continue in older children but usually subside. Half of these children go on to develop migraine in adolescence. Most have a family history of migraine. Caloric abnormalities are quite likely to be present if recordings are made. A very similar condition presents in a slightly younger age group as benign paroxysmal torticollis. All torticollis is not related to vertigo however. There is a suggestion that creatinine kinase levels are likely to be elevated in BPV of childhood, and measurement may be helpful in diagnosis.⁷ BPV has a very favourable long-term prognosis. In one study the condition had resolved by about eight years of age, and on long-term follow-up 21 percent had developed migraine but none had any vertigo or balance disorder.⁸ The differential diagnosis of a child or baby presenting with marked torticollis is large and varied and should include congenital torticollis, paroxysmal torticollis with vertigo, mastoiditis or neck abscess, skull base tumour and neurological extrapyramidal spasmodic torticollis or psychogenic spasmodic torticollis.

Basilar migraine

Migraine is a common multifactorial neurovascular disorder. Several genes have been discovered for migraine; the CACNA1A gene on chromosome 19p13, encoding for part of a neuronal calcium channel is one. Other loci and genes associated with migraine have also been described. Familial hemiplegic migraine has been similarly linked.

Migraine, in general, affects 5 percent of school-children and can occur at any age. Half of children with basilar artery migraine do not have headaches, but when present, the headaches are synchronous with the dizzy attacks in only one-third. Vomiting with attacks is common. The child is likely to be unwell for a few days at a time. If there is no headache the history of some transient neurological disturbance such as hemiparesis, ataxia or facial paresis will indicate the diagnosis. An important clue to this diagnosis is the family history; 85 percent have a history of a first-degree relative suffering from migraine. In one study into migraine-related vestibulopathy, common vestibular test abnormalities included a directional preponderance on rotational testing, unilateral reduced caloric responsiveness and vestibular system dysfunction patterns on posturography. Treatment was usually directed at the underlying migraine condition by identifying and avoiding dietary triggers and prescribing prophylactic antimigraine medications. Symptomatic relief was also provided using anti-motion sickness medications, vestibular rehabilitation and pharmacotherapy directed at any associated anxiety.⁹ Review of the symptoms of aura revealed the following: migraine with typical aura in 63.1 percent; migraine with prolonged aura in 4 percent; familial hemiplegic migraine in 6.5 percent, basilar migraine in 15.9 percent; and ophthalmoplegic migraine in 4 percent. The average age at the onset of migraine was 8.8 years and of the appearance of aura 10.9 years. The most frequent aura symptoms were visual. Hemiparaesthesia was seen in 34 percent, vertigo in 14.5 percent, hemiparesis in 13 percent and ataxia in 6.6 percent. Vaproate and flunarizine were effective for migraine prophylaxis.¹⁰

Electroencephalographic changes are seen during and shortly after a migraine attack but fully resolve in time. EEG, carried out within four hours of the onset of symptoms (initial stage), shows a diffuse polymorphic subdelta-delta activity. EEG, performed 16 hours after the onset of symptoms, shows delta-theta activity predominant over the occipital regions.¹¹

Video-nystagmography studies in children with migraine, undertaken during spontaneous nystagmus, gaze nystagmus, eye tracking test, optokinetic and positional nystagmus and caloric testing, showed that all patients with migraine had abnormalities in vestibular testing. Analysis of the results suggested a mainly central localization of vestibular dysfunction.¹²

There is an overlap between children with chronic tension type headache and migraine headache, usually without aura. Nausea, noise and light intolerance are common in these patients but vertigo is unusual.

Vestibular neuronitis

This presents as it does in adults, with acute severe vertigo, nausea and often vomiting but normal hearing.

Children recover more quickly from this disorder than do adults. Half of patients can have repeated episodes, although within a few years attacks become progressively less severe and are likely to cease.

Benign paroxysmal positional vertigo

While in adults BPPV most commonly occurs spontaneously or follows vestibular neuronitis sometime previously, in children it is rare and BPPV is more likely to occur following a head injury or marked whiplash injury. It has a good prognosis. In one study on children's temporal bones in Boston, 12.7 percent of paediatric temporal bones examined had basophilic deposits, many of them with otoconial crystals in the semicircular canals. That is much higher than the incidence in children who had any vertigo symptoms, a temporal bone finding mirrored for this condition in adults.¹³ The exact pathogenesis of BPPV is not yet fully explained.

Post-traumatic vertigo

The complaint of dizziness and headaches quite commonly follows head injury in children. The relatively high incidence of these persistent post-traumatic symptoms in children and adolescents presents a diagnostic challenge. It is often difficult to differentiate between functional complaints generated by psychological trauma or compensation seeking and an organic aetiology.¹⁴

Seizure disorders

Recurrent unprovoked seizures due to epilepsy are either generalized or localized (focal). Seizure disorders can give rise to vertigo in two ways: first, in the aura of a generalized (grand mal) fit; second, as vertiginous epilepsy or vestibulogenic epilepsy. In temporal lobe or occipital lobe focal epilepsy there may be transient loss of consciousness or amnesia; the child may describe the sensation of movement and may have visual or auditory hallucinations. There may be motor or emotional components. Convulsive epilepsies are generally unmistakable. Absence epilepsies may be recognized by the provocation of an episode during hyperventilation. Complex partial seizures in children can be difficult to distinguish from behavioural problems, shuddering attacks, paroxysmal vertigo, breath-holding spells, cardiogenic syncope, night terrors and movement disorders, such as paroxysmal kinesigenic choreoathetosis.¹⁵

A comparison of the elementary visual hallucinations of 50 patients with migraine and 20 patients with occipital epileptic seizures showed that in epileptic seizures they are predominantly multicoloured with circular or spherical patterns as opposed to the predominantly black and white linear patterns of migraine.

This simple clinical symptom of elementary visual hallucinations may be helpful in distinguishing between classic or basilar migraine and visual partial epileptic seizures, particularly in children.¹⁶ Referral to paediatric neurology is required if vertiginous epilepsy is suspected.

Psychogenic (conversion reaction) vertigo

Psychogenic dizziness should be diagnosed after excluding organic pathology. Sometimes seen in adolescents, more commonly girls, it is said to occur in children who are put under parental pressure to achieve. Recurrent fainting episodes can be seen in adolescence, when the possibility of a cardiac cause should be considered. In surdocardiac syndrome, for example, there is a prolonged QT interval, fainting and a risk of sudden death.

Psychogenic vertigo as a conversion reaction can be seen alone or in association with psychogenic hearing loss. The discrepancy between symptoms and findings in audiometric or vestibular tests is the essential clue for reaching a diagnosis of a conversion disorder. Referral to a psychiatrist may be necessary because many patients have problems in school or at home, and recovery may take a long time.¹⁷ [**/*]

Miscellaneous conditions with normal hearing

There are a number of other conditions which can mimic vertigo that are worth considering in the infant or child with unusual symptoms. These include toddler breath-holding attacks.

POISONING

In a child with dizziness, nausea and vertigo, among other symptoms, acute poisoning from plants, chemicals or drugs should be considered.

ATAXIA

Ataxia and other primarily neurological, hereditary or degenerative conditions are rare. They are discussed in a separate section (see later under Persistent imbalance and ataxia: central disorders).

VESTIBULAR CONDITIONS WITH ASSOCIATED HEARING LOSS

Otitis media with effusion and chronic suppurative ear disease

Glue ear may be detected in the clumsy child with poor balance who is more prone to falls than his siblings or

peers. Chronic suppurative otitis media (CSOM) with perforation and infections can influence general balance and CSOM with cholesteatoma carries the possibility of a fistula to the lateral semicircular canal or oval window accounting for dizziness or leading to suppurative labyrinthitis.

Menière's disease

Childhood or adolescent onset of Menière's disease, although uncommon, is well documented. In one series, sporadic Menière's disease began in childhood in less than 3 percent, although, in the less common familial Menière's disease in more than 9 percent, no doubt due to the phenomenon of anticipation. The clinical features are indistinguishable from those in adults; however, early onset tends to be associated with more aggressive disease and a likelihood of relatively early bilateral involvement.¹⁸

Associated temporal bone abnormalities and hearing loss

In numerous conditions and syndromes there is sensorineural hearing loss with temporal bone anomalies. In only a small number of these conditions are children likely to present with vestibular symptoms. Vision remains the most important special sense in acquiring balance. Children with bilateral vestibular impairment may be delayed somewhat in motor development but rarely present with vertigo. Not surprisingly, in conditions where there is abnormal or absent vestibular development and visual loss, children are more likely to present with balance disturbances. Children with Usher's syndrome have vestibular hypofunction and may therefore have balance difficulties when vision is also impaired.

In CHARGE association (see Chapter 82, Nasal obstruction in children), there are frequently abnormalities, for example a primitive otocyst, and such children may have absent semicircular canals and an aberrant facial nerve. A study from Ann Arbor researched patients with severe sensorineural hearing loss and agenesis of the semicircular canals. Most had CHARGE syndrome, some were nonsyndromic, and one had Noonan's syndrome. They did not present with vertigo.¹⁹ X-linked hereditary deafness is another example in which vestibular symptoms are uncommon despite vestibular hypofunction. Vestibular hypofunction may be present in Down's syndrome.

Enlarged vestibular aqueduct syndrome

Enlarged vestibular aqueduct syndrome is a rare congenital anomaly; vestibular disturbance is uncommon but is seen in 4 percent of children. Fluctuant and progressive

sensorineural hearing loss is the norm and is bilateral in 87 percent of cases. A vestibular aqueduct radiologically wider than 1.5 mm at its midpoint or wider than 2 mm at the operculum is defined as enlarged.²⁰ Most patients maintain stable hearing in at least one ear over a four-year period. It can occur in nonsyndromic conditions but is also found in 50 percent of patients with Waardenburg's syndrome (types 1 and 2), in which there may be significant widening of the vestibular aqueduct at its midpoint together with other temporal bone anomalies.²¹ These children tend to have profound or severe hearing loss. Up to 30 percent of children with Waardenburg's syndrome have vestibular impairment and some experience episodic vertigo. Enlarged vestibular aqueduct syndrome is also seen in Pendred and the branchio-otorenal syndromes, often with an associated Mondini deformity in the former. Patients with enlarged vestibular aqueduct syndrome may show an autosomal recessive inheritance (see Chapter 66, Molecular otology, development of the auditory system and recent advances in genetic manipulation).²² Avoidance of head injuries is recommended, but may not influence the progression of deafness. The pathogenesis is ill-understood. Surgery to occlude the vestibular aqueduct remains controversial. Conservative management is advised.

The patent cochlear aqueduct

The cochlear aqueduct at its narrowest portion is 0.14 mm wide. It widens as it opens into the posterior fossa with a very variable size at this point. The late Peter Phelps, who had extensive experience in the histopathology of temporal bones, stated that after study of 1400 normal temporal bones and 29 with dysmorphic labyrinths he had failed to show a dilated cochlear aqueduct, and believed that sensorineural deafness attributed to this, in fact, related to defects at the fundus of the internal auditory canal (Phelps P, personal communication).

Dehiscent superior semicircular canal syndrome

Dehiscent superior semicircular canal syndrome has been described but is quite rare. It can be demonstrated on high resolution CT scanning. Typically, vertigo or oscillopsia is evoked by loud noises or by stimuli that result in changes in middle ear or intracranial pressure. The Tullio phenomenon (vertigo in response to sound) and Hennebert's sign (a positive fistula test with a normal middle ear) may therefore be found. Three-quarters of patients also experience chronic dysequilibrium – often the most debilitating symptom.²³ The condition may also present with an apparent conductive hearing loss. Evoked eye movements, by Valsalva manoeuvre against pinched nostrils, tragal compression or sounds over 100

dB at 500–2000 Hz, produce vertical and torsional components. Surgical repair via the middle fossa approach is successful.

Perilymph fistulae

Perilymph fistulae in children are usually seen in association with temporal bone anomalies and pre-existing severe or total hearing loss in the affected ear. They may present with recurrent meningitis or with cerebrospinal fluid (CSF) behind the tympanic membrane. Perilymph fistulae can arise directly from blunt trauma to the middle ear or from temporal bone fractures and, iatrogenically, after ear surgery for CSOM or poststapedotomy. More rarely, marked barotrauma may lead to a fistula from the round or oval windows. In all these situations surgical exploration to seal the fistula is indicated. Spontaneous perilymph fistula in the normal temporal bone however is probably almost never seen.

In the late 1980s there was a vogue for clinically diagnosing a spontaneous perilymph fistula in children and adults who presented with symptoms of hearing loss, vertigo and sometimes tinnitus. These patients were subjected to surgical exploration of the middle ear with sealing of the apparent fistula. In general, the hearing outcomes from surgery did not seem to correlate with the finding of a fistula and, indeed, it can be very difficult at surgery to be sure if there is any real perilymph leak. To address some of the problems inherent in the diagnosis and treatment of perilymph fistulae, records of patients operated on at the House Ear Clinic over 12 years were reviewed retrospectively. Eighty-six patients were surgically explored for fistulae during this period. Thirty-five (40.7 percent) fistulae were found and 51 ears were patched whether fistulae were found or not. Of the 80 patients who were seen for follow-up, 35 (43.8 percent) were subjectively better and 45 (56.2 percent) were the same. Although the number of fistulae found and the number of patients improved were similar, the composition of the two groups was different. On the basis of audiometric results, improvement in hearing happened in only 18.7 percent of patients. None of the demographic factors or diagnostic tests was predictive of either the presence of a fistula or the therapeutic outcome.²⁴

Another retrospective study by Bluestone *et al.* on patients undergoing perilymph fistula repair compared pre- and postoperative hearing levels, vertiginous complaints and recurrences. In 92 percent of ears there was either stabilized or improved hearing and in 3 percent a decrease was noticed, but this was much later and believed not to be related. The results were similar however in the nonperilymph fistula ears, of which 95 percent had stabilized or improved hearing and, again, 3 percent had a much delayed decrease. Of the children with vertiginous complaints before surgery, 91 percent were improved or stable. Only one child felt somewhat

worse, but, as with hearing loss, this was later than six months after the surgery.²⁵

In yet another series of cases operated on for suspected perilymph fistula, ears with a surgically demonstrated fistula and sensorineural hearing loss had either flat or downward-sloping audiograms. At follow-up, vestibular symptoms were found to be eliminated or improved in 96 percent of cases with surgically demonstrated fistulae and in 68 percent of cases in which no fistula was detected at tympanotomy, but hearing improved significantly in only one ear (4 percent) of the former group and in five ears (20 percent) of the latter group.²⁶

To conclude, perilymph fistulae can be a cause of hearing loss, vertigo or tinnitus and these symptoms may be fluctuant and possibly progressive. There is currently no good diagnostic test for a small fistula. In the paediatric population the most frequent cause is a congenital fistula. Severe or profound hearing loss is, in this instance, always associated with temporal bone anomalies when a perilymph/CSF leak may be present with fluid behind the tympanic membrane. A defect in the stapes and continuity with the fundus of the internal auditory meatus is one such example. This can be found with a true Mondini deformity in which case some hearing from the basal turn of the cochlea is possible. These cases will require surgical exploration and closure of the leak, not to improve or restore hearing but in an attempt to prevent subsequent meningitis.

Traumatic perilymph fistulae with normal temporal bone anatomy are rare. They are described following head injury and penetrating injury to the middle ear with or without temporal bone fracture, but diagnosis is difficult.²⁷ A persistent perilymph fistula following ear surgery requires re-exploration. Severe barotrauma can also produce a fistula from the round window or oval window. Clinical suspicion will lead to the decision to explore the ear surgically. More obvious bony erosion with fistula is not infrequently encountered in the presence of cholesteatoma. Exploration and closure of the fistula is indicated. Spontaneous perilymph fistula, in the absence of head injury, direct injury or barotrauma can be virtually discounted. [***/**]

Drug-induced vertigo or imbalance

Ototoxic medications, in particular aminoglycosides, can cause marked vestibular dysfunction with acute vertigo at the time of administration or poor balance, ataxia and motor delay. These drugs might have been administered systemically prenatally to the mother or in post-natal life, but occasionally topically in the presence of a chronic perforation or grommets. Fortunately, however, hearing loss from systemic aminoglycosides given to an infant is unusual. Some degree of vestibular loss may be more common and underdiagnosed. Streptomycin and gentamicin are more selectively vestibulotoxic. In one study,

children who had previously been treated with streptomycin commonly showed delay in walking.²⁸

Antimalarials such as mefloquine, which is only slowly cleared from the body, can cause dizziness or hearing loss. Platinum-based cytotoxic agents can cause ototoxicity, usually high tone hearing loss and tinnitus rather than dizziness.

Miscellaneous conditions with hearing loss

Infectious aetiologies such as congenital cytomegalovirus (CMV) infection can include sensorineural hearing loss with vestibular symptoms and metabolic diseases such as Hurler's syndrome can be seen with a retrocochlear type of hearing loss and vestibular impairment. Herpes zoster oticus can occur in children.

PERSISTENT IMBALANCE AND ATAXIA: CENTRAL DISORDERS

Toddlers may present with imbalance and a delay in motor development, or with a subsequent deterioration in vestibular function. They can have falls, fear of the dark, abnormal gait and vomiting. Primary developmental delay with motor delay and poor balance suggests a congenital or early acquired neurodevelopmental disorder, while regression of balance and locomotor function that was previously acquired indicates the need to exclude a space-occupying lesion such as meningioma or medulloblastoma. A family history of NF2 would raise suspicion. Any severe illness or even major surgery in a baby or smaller child will not infrequently lead to temporary loss of previously acquired skills such as the ability to walk.

ATAXIA

Ataxia is a common mode of presentation of cerebellar, posterior column and vestibular disease in children. The aetiology of ataxia covers a broad range, from infections to rare hereditary metabolic diseases. The importance of recognizing potentially reversible conditions such as vitamin E deficiency and Refsum's disease has been stressed.²⁹

Hereditary cerebellar ataxia

Hereditary cerebellar ataxia present with a slowly progressive ataxia although a posterior fossa tumour must be excluded by imaging. Cerebellar disorders display a variety of inherited and sporadic causes. Advances in genetics have led to the successful classification of over 20 forms of autosomal dominant and recessive cerebellar ataxia with variable phenotypes and have shed light on the underlying pathophysiology of many of these

disorders. Successful disease-modifying or symptomatic treatments for these conditions, thus far, have remained limited.³⁰

Refsum's disease

Refsum's disease is a disorder of lipid metabolism with pigmentary retinopathy, demyelinating neuropathy, ataxia and hearing loss. There is progressive difficulty in walking which develops between the ages of four and seven years. In some cases the site of the hearing abnormality in Refsum's disease may be 'post-outer hair cells'.³¹

Charcot-Marie-Tooth disease

The most common hereditary degenerative condition is Charcot-Marie-Tooth disease. Inheritance is autosomal dominant. Perineal muscle atrophy is usual, congenital sensorineural deafness is present in some cases and there can be vestibular weakness. These children develop spinal scolioses and pes cavus.³²

Acute cerebellar ataxia

Acute cerebellar ataxia occurs, usually in the first three years of life, in a child who was previously normal. It follows a viral febrile illness a few weeks beforehand. There is sudden ataxia, and the condition may take a number of months to resolve or leave some permanent sequelae.

Chiari malformations

Type 1 Chiari malformation is characterized by cerebellar tonsil herniation through the foramen magnum. Children most commonly present with bilateral vocal cord paralysis and associated upper airway obstruction but they can also present with positional vertigo and a central type of nystagmus. The condition can be more severe and associated with syringomyelia, in which case there can be neurological improvement after foramen magnum surgical decompression. Type 1 may present to otolaryngologists.

Type 2 Chiari malformation is the same as type 1, except that in addition there is a noncommunicating hydrocephalus and lumbosacral spina bifida. Type 3 can have any of these features but with cervical or occipital bifida. Children with types 2 and 3 have widespread neurological abnormalities and are unlikely to attend ENT clinics.

Miscellaneous conditions

Demyelination can present in post-pubertal children, in which case vertigo is quite commonly seen. NF2 with

posterior fossa meningiomas or vestibular schwannoma are occasionally seen in children, and other intracranial posterior fossa lesions such as medulloblastoma may present with ataxia and vomiting.

Infectious causes

Infectious causes include Lyme disease. Viral infections include meningitis, Coxsackie A and B and echovirus; they can involve the central nervous system with vertigo, nystagmus and cerebellar signs. HIV infection is another possible cause. Bacterial infections include primary meningitis, labyrinthitis as a complication of meningitis or CSOM and tertiary or congenital syphilis. [**/*]

TREATMENTS FOR VERTIGO

Medical treatments

The causative condition should be treated directly if possible. The mainstay of treatment, however, is usually an explanation to the parents and the child and reassurance.

Symptomatically, vestibular sedatives can be helpful. Antihistamines such as cyclizine or cinnarizine can be taken for more prolonged attacks. Hyoscine patches have been advocated and domperidone is helpful for associated sickness.

Dopamine antagonists including phenothiazines such as prochlorperazine are effective vestibular suppressants. However, there is a greater risk of extrapyramidal side effects when using phenothiazines, especially in children. They should be avoided in babies under 10 kg. Should these medications lead to extrapyramidal effects such as oculogyric crisis, it can be treated acutely with the antagonist, procyclidine, by injection.

HT3 antagonists such as ondansetron are powerful antiemetics which block serotonin binding at vagal afferents in the gut and in the regions of the central nervous system (CNS) involved in emesis, including the chemoreceptor trigger zone and the nucleus tractus solitarius. Although principally used in postoperative nausea and vomiting or with cytotoxic drug therapy, they may have a role in the vertiginous child, especially if vomiting.

Migrainous vertigo can be treated with metaclopramide, or serotonin 5-HT₁ receptor agonists such as sumatriptan. Rizatriptan is reported to be more effective than other drugs of this class and other simple analgesics.³³ Dietary exclusions can be helpful. Preventative measures, if necessary, would be those currently recognized – pizotifen or propranolol – and if those fail, a neurologist might prescribe anticonvulsants.

Menière's disease may be treated with betahistidine, a low salt diet and possibly diuretics or intermittently by dehydration therapy such as Glycerol taken orally. Surgery

may occasionally be indicated in severe variants of the disease.

The seizure disorders are usually well controlled with anticonvulsants under the paediatric neurologist's guidance.

Physical treatments for vertigo

If there is benign positional vertigo, the Epley manoeuvre (see Chapter 240d, Vertigo: clinical management and rehabilitation) or the Brandt-Daroff exercises can be employed successfully. Other vestibular rehabilitation exercises for children who have suffered unilateral labyrinthine damage might be helpful in achieving full central compensation and in speeding recovery.

Surgery for vertigo

Surgery relates to that indicated for specific underlying conditions. Unilateral glue ear with poor balance can be corrected by insertion of grommets (preferably bilaterally, the contralateral ear as a prophylactic measure).

If there is a perilymph fistula from barotrauma, middle ear or mastoid disease, or following surgery, that should be explored and closed. Likewise, suppurative ear disease and congenital or acquired cholesteatoma will require tympanomastoid surgery.

A perilymph/CSF fistula from congenital temporal bone anomalies should be closed surgically in an attempt to prevent future meningitis.

Childhood-onset Menière's disease tends to run an aggressive course with debilitating bilateral disease later in life. Destructive surgery is not advised at an early stage although endolymphatic sac decompression and drainage may have a role. [**/*]

KEY POINTS

- Vertigo results from a mismatch of three different sensory inputs, i.e. vision, proprioception and the vestibular system.
- Presentation of balance disorders in children differs from that in adults; very young children cannot complain of vertigo.
- Fifty percent of cases of childhood dizziness and imbalance are caused by one of the three most common causes: BPV of childhood, migraine or OME.
- Adult causes of vertigo are seen in older children/adolescents.
- The mainstay of treatment is reassurance; symptomatic control with medication such as cinnarizine or antimigraine treatments is usually effective.

Best clinical practice

- ✓ A full history, neurologic examination and audiometry are required in assessing any child with vertigo. [Grade C/D]
- ✓ Middle ear disease and congenital sensorineural conditions with vestibular deficits should be excluded. [Grade C/D]
- ✓ Posterior fossa disease must be excluded where there is ataxia. [Grade C/D]
- ✓ In some cases, a full blood count, inflammatory markers, glucose, creatinine kinase, thyroid function and special serological tests are helpful. [Grade C]
- ✓ High resolution CT scanning of the temporal bones and an MR brain scan are often indicated for dizziness with hearing loss. [Grade C]
- ✓ An MR brain scan is indicated for ataxic conditions. [Grade C]
- ✓ Special vestibular tests including bithermal caloric stimulation and rotational chair testing can be helpful in reaching a diagnosis and planning treatment. [Grade B]
- ✓ Referral to a paediatric neurologist is recommended if the diagnosis of a seizure disorder or basilar migraine is considered probable. [Grade D]
- ✓ Treatment should comprise explanation and reassurance about the condition and symptomatic medical treatment for the vertigo. [Grade D]
- ✓ Surgical treatment is recommended for significant balance disturbance with OME and for CSOM with cholesteatoma as well as for a persistent perilymph fistula from other causes. [Grade D]

Deficiencies in current knowledge and areas for future research

- The value of bithermal caloric tests, video-nystagmography and rotational chair tests has not been demonstrated in the varied paediatric population with vertigo.
- The benefit of vestibular rehabilitation exercises over encouraging straightforward everyday activities has not been studied in children's treatment regimens.
- Motion sickness has been subject to observational studies and effects of drug treatments but further research into aetiology and other treatments could be profitable.
- The role and efficacy (if any) of HT3 antagonists such as ondansetron in the management of childhood vertigo has not been studied.

SEARCH STRATEGY

The data in this chapter are supported by a PubMed search using the key words facial paralysis, otitis media, congenital facial paralysis, ear trauma, facial nerve injury, Wegener’s, Bell’s palsy and parotid surgery. The focus was restricted to neonates and children.

INTRODUCTION

Bell’s palsy remains the most common aetiology for facial paralysis in children¹ although it is much less common than in adults. May *et al.*,² in their study of 170 patients aged from birth to 18 years, found the following aetiology for facial paralysis: Bell’s palsy (42 percent), trauma (21 percent), infections (13 percent), congenital (8 percent) and neoplasm (2 percent).

Bell’s palsy in children is considered to have a better prognosis than in adults, regardless of treatment.

EMBRYOLOGY AND APPLIED ANATOMY OF THE FACIAL NERVE

Knowledge of the embryology and developmental anatomy of the facial nerve allows for a clear understanding of the various anomalies and clinical presentations of disorders of the facial nerve. The reader is referred to Chapter 65, Head and neck embryology.

By the third week of embryonic development the facioacoustic crest is visible on the dorsolateral aspect of the hindbrain just cranial to the otic placode. The otic placode forms the otocyst giving rise to the membranous labyrinth in the fourth week and the facial nerve becomes distinct. The geniculate ganglion has formed by the fifth week (**Figure 80.1**). The facial nerve divides into its main trunk descending into the second branchial arch and the chorda tympani, which being the pretrematic branch curves cranially into the first branchial arch. A pretrematic branch of a cranial nerve is one that supplies the arch preceding the arch to which the cranial nerve belongs. The chorda tympani and the main trunk of the facial nerve are equal in size at this stage. Malformations of the branchial arches are associated with anomalies of the chorda tympani, such as elongation of the posterior canaliculus, reduplication and low position of the nerve.^{3,4}

The facial nucleus is formed by neuroblasts in the pons, with the sixth nerve nucleus in close proximity. As the brain develops and the pons expands, the sixth nucleus ascends so that the facial nerve fibres have to

whirl round the sixth nucleus thus forming an internal genu. Clinically, therefore, an inflammatory or vascular event in this part of the brain will necessarily involve both these nerves. In developmental anomalies such as Mobius syndrome there is agenesis of the facial nucleus and, among other defects, there is also agenesis of the sixth nucleus.⁵

The geniculate ganglion has a separate origin from the facial nerve.⁶ It is well defined by the seventh week and gives rise to the sensory roots that form the nervus intermedius. As the main facial trunk descends down the second branchial arch there is caudal movement of the first arch due to rapid expansion, producing the horizontal segment and the first and second genu of the nerve, with the greater superficial petrosal nerve acting as an anchor. Proctor and Nager's seminal papers^{7,8} describe the many variations encountered in the vertical segment of the facial nerve including a bipartite nerve, an anteriorly displaced nerve or one with a posterior hump. Failure to appreciate an anomaly of the facial nerve during surgery can have serious consequences.^{9,10,11,12}

Conditions related to malformations of the first or second arch, such as Treacher Collins and Goldenhar

syndromes, will usually mean that the facial nerve is abnormal too. At birth, the normal temporal bone has no mastoid process and an incomplete tympanic ring. The 'u-shaped' tympanic ring has nodular prominences on each arm, which separate the annulus from the future external canal and the foramen of Huschke (**Figure 80.2**). By the end of the first post-natal year these processes fuse, lengthening the canal (**Figure 80.3**). The foramen usually closes some time later. In the newborn the chorda tympani and the facial nerve may exit through the stylomastoid foramen. The mastoid process and external auditory canal are undeveloped so the nerve is very superficial.

The mastoid process develops and reaches adult proportions by the age of 12 years. In neonates and small children the second genu of the facial nerve is more acute and courses more laterally. The most common variation in the course of the facial nerve canal involves the tympanic segment; the bony wall may be dehiscent in 35–55 percent of the population, particularly above the oval window.^{7,8,13,14} Acute suppurative otitis media in neonates and children may therefore present with facial paralysis from neuropraxia or bacterial infiltration of the

Figure 80.1 The foetal head aged five weeks.

Figure 80.2 The neonatal temporal bone.

Figure 80.3 The temporal bone of a one-year-old child.

nerve sheath within an enclosed middle ear. Dehiscence of this segment of the facial nerve may be associated with a persistent stapedial artery in its course from the tympanic cavity to the middle cranial fossa where this becomes the middle meningeal artery.^{15, 16} The foramen spinosum is absent on the side of the persistent stapedial artery on plain x-ray or computed tomography (CT).

On leaving the stylomastoid foramen the facial nerve enters the parotid gland in a more anterior location than in the adult, as the parotid gland is smaller and more anteriorly placed.¹⁷ The nerve divides into two main divisions and these give rise to branches that supply the face and the upper neck muscles. The lower division of the facial nerve in young children runs very superficially over the angle of the mandible and can be damaged by a skin incision during surgery. Surgery of the parotid region in children requires an understanding of the differences between adult and child facial nerve topography (Table 80.1).

DIAGNOSIS

This is discussed in general terms in this section. Individual conditions are covered under separate headings.

History taking and examination

A detailed clinical assessment is important in the diagnosis of facial paralysis. There may be good muscle tone so that it is difficult to identify the paralysis until the child cries. Associated symptoms that teenagers with facial paralysis may volunteer will not be available in a younger child. Careful attention to the mother’s story will be rewarding.

Examination should include careful assessment of each branch of the facial nerve and whether the paralysis is complete or incomplete. The forehead wrinkles are absent and the eyebrow droops in lower motor neurone paralysis. The lower lid tends to fall away from the globe with tears collecting in the eye and spilling onto the face. The cheek may sag and the nasolabial fold may be lost. Speech may change as plosives are distorted with air blowing out on the paralysed side. The appearance of the nonparalysed side of the face is also characteristic as unbalanced muscle action accentuates the difference. The House Brackmann grading has the advantage of currency and may be used in children. Otoscopy is usually possible in even the smallest baby and signs of inflammation should be looked for in the head and neck. Other anomalies of the head and neck and the cranial nerves are noted.

Table 80.1 Differences in the anatomical relationship of the facial nerve in adults and children.

Child	Adult
Absent mastoid process and incomplete tympanic ring. The chorda tympani may exit through the stylomastoid foramen with the main trunk in the neonate	Mastoid process present and tympanic ring is complete by adolescence. Chorda tympani exits separately and proximal to the stylomastoid foramen
Second genu of the facial is more acute and more lateral	Second genu of facial nerve less acute and more medial
Nerve trunk on exit from stylomastoid foramen is more anterior and lateral	Parotid is more posteriorly placed and the nerve trunk is less anterior and deeper
Nerve very superficial over angle of mandible	Nerve superficial over angle of mandible

Investigations

Imaging of the facial nerve in children may be useful in delineating the site of neural injury. Indications include persistent paralysis, trauma and suspected nerve involvement in systemic diseases.

Magnetic resonance imaging (MRI) is the only modality that demonstrates the facial nerve comprehensively from the pons to the parotid gland; with gadolinium enhancement it is capable of showing inflammatory changes. CT makes it possible to see bony detail and is ideal when facial nerve involvement is in the middle ear cleft, see also Chapter 102, Imaging in paediatric ENT. [**/*] [Grade C/D]

Electrophysiological tests allow objective assessment of function. Eavey *et al.*¹⁸ found that 95 percent of children can be successfully tested with electroneurography. Waveform amplitude and morphology were consistent with adult values except in infants. The most clinically helpful use of this test is objectively to assess facial nerve function, once spontaneous motion is lost in acquired paralysis or if it had never been seen in congenital paralysis. The authors maintain that the test is not an absolute predictor for return of function but that the added data when used with clinical information make assessment of prognosis more rational.

Glasscock and Shambaugh¹⁹ recommend a muscle biopsy in neonates with facial paralysis when the electromyography is silent. If muscle is found, early reanimation is advisable.

CONGENITAL FACIAL PARALYSIS

Syndromic and nonsyndromic forms of developmental facial paralysis occur. These may be unilateral or bilateral, complete or incomplete. Prognosis is poor.^{20,21} Craniofacial anomalies associated with the first and second arch derivatives are common in this form of facial paralysis. The reader is referred to Chapter 78, Craniofacial anomalies: genetics and management.

Nerve exploration is unrewarding in this situation.²² Reanimation may be considered. There is a wide range of procedures for reanimation; the most desired neural tissue source for rejuvenation of the paralysed face is achieved by direct reanastomosis or interpositional grafting. Carr *et al.*²³ reviewed 186 children with congenital facial paralysis (60 percent male and 85 percent with bilateral paralysis) and found 29 in whom reanimation was performed (24 females and five males). All five males and nine females had unilateral isolated facial nerve paralysis. Fourteen females had bilateral paralysis; only half of these were isolated. Other involved cranial nerves included abducens, hypoglossal, oculomotor and trochlear. The cranial nerve least likely to be involved was the accessory nerve, suggesting that this may be a reliable donor for reanimation procedures. As previously stated,

early reanimation is advised by Glasscock and Shambaugh¹⁹ if muscle is found on biopsy in neonates with facial paralysis when electromyography is silent.

Mobius syndrome

This is a rare cause of facial paralysis in neonates. It is characterized by the absence or underdevelopment of the VIth and VIIth cranial nerves. It may be unilateral or bilateral. Agenesis of the facial nucleus is suspected, hence the VIth nerve involvement. Other cranial nerves may also be involved. Autism and mental retardation may be seen in one-third of these patients.⁵

Goldenhar syndrome

Goldenhar syndrome (oculoauriculovertebral dysplasia) is a wide spectrum of congenital anomalies that involves structures arising from the first and second branchial arches.²⁴ Involvement of the internal auditory meatus and the VIIIth nerve has been reported²⁵ as well as progressive hearing loss.²⁶ (See Chapter 78, Craniofacial anomalies: genetics and management.)

Asymmetric crying facies

Congenital asymmetric crying facies is an uncommon condition caused by congenital hypoplasia or agenesis of the depressor anguli oris muscle on one side of the mouth. Although the functional deficit is small, the anomaly may be associated with cardiovascular, head and neck, musculoskeletal, respiratory, gastrointestinal, central nervous system or genitourinary anomalies in 45 percent of cases.²⁷

CHARGE syndrome

The acronym CHARGE is used to describe specific congenital birth defects in children: colobomata, heart defect, atresia of the choanae, retarded development, genital hypoplasia and ear anomalies and hearing loss. Facial nerve dysfunction has been noted in 38 percent of patients,²⁸ and an aberrant course may interfere with cochlear implantation.²⁹ Many children also have feeding and swallowing difficulties, and facial paralysis and pharyngeal incoordination may be important diagnostic indicators of CHARGE association.³⁰

Familial facial paralysis

Familial congenital facial paralysis has been reported in three male members from three generations of one family.³¹ The paralysis has become more pronounced with every successive generation. [**/*] [Grade C/D]

ACQUIRED FACIAL PARALYSIS

Infections

ACUTE OTITIS MEDIA

Acute otitis media in neonates and children can present with facial paralysis. This is usually incomplete but the paralysis may progress in the first two to three days of onset. There is suppuration in the middle ear behind an intact tympanic membrane. This may appear red and bulging. The child may be toxic but is typically not unwell. In some cases, where antibiotic have been given, the signs of acute inflammation may not be pronounced. The underlying pathology may be an erosion of the bony Fallopian canal or congenital dehiscence and nerve inflammation. Spread along structures such as the stapedial tendon, chorda tympani or the posterior tympanic artery have been suggested. Moreano *et al.*¹⁴ studied 1000 temporal bones and noted at least one facial canal dehiscence in 56 percent of temporal bones with the most common site of dehiscence being the oval window area. They introduced the concept of microdehiscence of the facial canal and found this in one-third of the temporal bones. The most common pathogen in middle ear cleft infections in children is pneumococci (80 percent).³² A wide myringotomy and systemic antibiotics are the initial treatment (Figure 80.4). [Grade D] If mastoiditis is suspected, a CT scan and a cortical mastoidectomy may be needed. There is usually full recovery of facial nerve function.

CHRONIC OTITIS MEDIA

Facial paralysis in chronic otitis media is very uncommon. Sheehy *et al.*³³ report 11 cases of facial paralysis out of 1024 patients with chronic middle ear disease and cholesteatoma. Complications of chronic middle ear disease including facial paralysis are more common in the developing world.³⁴

LYME DISEASE

This multisystem disease is caused by the tick-borne spirochaete *Borrelia burgdorferi*.³⁵ A skin lesion appears after an incubation period of one to four weeks. Ipsilateral or bilateral facial paralysis may appear weeks or months later in 11 percent of cases.³⁶ A report from Connecticut, an endemic area, describes Lyme disease as the cause of more than 50 percent of facial paralysis in children.³⁷ Serological tests with enzyme-linked immunosorbent assay to detect immunoglobulin G and M antibodies are used for diagnosis. Doxycycline is the oral antibacterial of choice, while amoxicillin and cefuroxime are alternatives that may be preferred in young children. Tick avoidance has long been the mainstay for preventing Lyme disease.³⁸

© Hodder Arnold / Scott-Brown 7E

Figure 80.4 (a) Facial paralysis in a neonate from acute otitis media; (b) the state of the eardrum.

VIRAL INFECTIONS

Recrudescence of herpes zoster virus in the geniculate ganglion leads to the classical syndrome of Ramsay Hunt. The disease is uncommon in children. Hato *et al.*,³⁹ in a retrospective study of 52 children with Ramsay Hunt syndrome, found that facial paralysis was milder, complete recovery of the function more likely (79 percent) and associated cranial neuropathies less common in children than in adults. The timing of vesicle appearance tended to be delayed in children. The disease was rare in preschool children but relatively more common in older children. Treatment with oral or intravenous acyclovir and prednisolone has been recommended.^{40, 41} Facial paralysis has been noted in Epstein-Barr virus infection and this may be bilateral in 40 percent of cases.⁴² Facial palsy is an early ENT manifestation of human immunodeficiency virus infection and is seen in 11 percent of cases.⁴³

TUBERCULOSIS

The presence of facial paralysis with purulent otorrhoea that does not respond to conventional antibiotics should

alert the physician to the possibility of tuberculosis. Antituberculous chemotherapy early in the disease may reduce the need for radical surgery.^{44, 45} CT scan is reported to be of value in the diagnosis of facial paralysis due to tuberculosis.⁴⁶

Traumatic

BLUNT TRAUMA

Perinatal trauma

Birth-related trauma is a known cause of facial paralysis. The incidence of facial palsy in the newborn is 1.8 in 1000, the majority associated with forceps delivery.⁴⁷ In their report on neonatal facial paralysis, Smith *et al.*⁴⁸ found 74 of 95 cases to be secondary to trauma associated with pregnancy and delivery. The diploic bone of the infant mastoid process, the paper-thin bone covering the facial nerve and the very superficial position of the marginal mandibular branch over the mandible all add to the problem. The pressure of the mother's sacrum on the infant facial nerve may also contribute.

In differentiating between congenital and perinatally acquired facial paralysis the history and physical examination usually suffice. A history of forceps delivery, a baby weighing over 3.5 kg, a primipara mother, prolonged labour and the absence of associated craniofacial anomalies point to perinatal trauma as the cause. The presence of bruising on the side of the face and the mastoid region are suggestive of birth trauma as are other complications associated with birth.

Electrophysiological tests may be used to aid diagnosis; voluntary action potentials on electromyography indicate muscle innervation. Electromyography performed after ten days of paralysis will show fibrillation or polyphasic potential in traumatic cases and absent electrical activity in congenital facial paralysis.⁴⁹ A CT scan may show a concealed fracture of the temporal bone.

Temporal bone fracture

An injury to the skull may cause temporal bone fracture. The fracture may be longitudinal, transverse or a combination of both. Classically, longitudinal fractures cause conductive hearing loss whereas transverse fractures usually cause irreversible sensorineural deafness. One-third of fractures are transverse and these have associated facial paralysis in 50 percent of cases. Longitudinal fractures are more common and although the incidence of facial paralysis is less (20 percent), longitudinal fractures cause more facial paralysis than transverse fractures. As discussed previously (see Embryology and applied anatomy of the facial nerve) the greater superficial petrosal nerve in the region of the geniculate ganglion tethers the facial nerve. In head injury the sudden deceleration creates a shearing force on the facial nerve leading to damage. Lee *et al.*⁵⁰ reviewed 72 children with

temporal bone fractures ranging from 6 months to 14 years of age, with a bimodal distribution with peaks at 3 and 12 years of age. The most common causes of fractures were motor vehicle accidents (47 percent), falls (40 percent), biking accidents (8 percent) and blows to the head (7 percent). Common presenting signs and symptoms⁵¹ include hearing loss (82 percent), haemotympanum (81 percent), loss of consciousness (63 percent), intracranial injuries (58 percent), bloody otorrhea (58 percent), extremity fractures (8 percent) and facial nerve weakness (3 percent). The diagnosis of temporal bone fractures is best made clinically and radiographically. The early care of temporal bone fractures is directed toward the treatment of cerebrospinal fluid otorrhoea and immediate-onset facial paralysis. The delayed care is primarily concerned with hearing rehabilitation.⁵² Surgical exploration as an option remains controversial, with no randomized controlled study available. It does seem reasonable, however, to explore when nerve entrapment is suspected or where the integrity of the nerve is compromised.

PENETRATING TRAUMA

Injury to the face may damage the facial nerve or one or more of its branches. This may be the result of falling on to a sharp object or a dog bite. The wound needs to be explored and the degree of damage established. This will allow repair with the functioning distal branches in a clean wound. Local control of infection should precede repair in a contaminated wound. [**/*] [Grade C/D]

IATROGENIC TRAUMA

Ear surgery

Mastoid surgery carries a higher risk of injury to the facial nerve in children, even in experienced hands. This is because of the absence of the mastoid process in small children and the superficial position of the facial nerve, which is at risk from a low incision. The operating space within the mastoid cleft is small and if, in addition, an anomaly is encountered, the problems multiply. The injury may not be identified at the time of surgery and may become obvious when the patient is awake.⁵³ The most common site of injury is the tympanic segment and the second genu of the nerve.^{53, 54} Anomalies of the facial nerve encountered in patients with congenital malformation of the middle ear include displacement of the nerve and lack of bony cover.¹⁰ A low-lying tegmen in a sclerotic mastoid is particularly serious and requires skill to protect the nerve at the second genu when drilling in this restricted area. The presence of granulating disease in revision surgery may obscure the usual landmarks and put the nerve at risk. Erosion of the bone by cholesteatoma and its spread to the supra tubal recess⁵⁵ puts the geniculate ganglion and the first genu of the facial nerve

at risk of injury during disease clearance in the anterior attic. In patients with atresia or stenosis of the external canal, the facial nerve may be damaged in its vertical segment owing to the vertical segment being relatively lateral to the tympanic annulus. Intraoperative monitoring is advisable. [Grade D] Injury to the facial nerve and the chorda tympani are recognized complications of cochlear implantation surgery.^{56, 57, 58}

Parotid surgery

The superficial course of the facial nerve in infants and the underdevelopment of surrounding structures mean that the standard techniques for identification of the facial nerve trunk in adults could jeopardize the nerve in children. An alternative technique for identifying the facial nerve has been proposed by Farrior and Santini.¹⁷ Anatomic dissection demonstrates that the facial nerve trunk can be consistently found in a triangle formed by the sternocleidomastoid muscle, posterior belly of the digastric muscle and the cartilaginous ear canal. As in adults, the nerve canal can be identified in the mastoid cavity and followed into the neck. Unlike in adults it is inadvisable to use retrograde dissection of the marginal mandibular branch to find the trunk. [Grade D] Surgery for nontuberculous mycobacteria of the parotid gland and adjacent lymph nodes requires very careful dissection to preserve the facial skin and the nerve (Figure 80.5).

Branchial cleft sinus and fistula excision

The variable relationship of the branchial cleft sinus and fistula with the facial nerve makes the nerve vulnerable to injury during surgery. Very careful dissection with intraoperative monitoring is required. D'Souza *et al.*⁵⁹ reviewed the available English, French and German literature between 1923 and 2000 and found 158 cases with fistulae and sinuses. The fistulous tracts were more likely to lie deep to the facial nerve compared with sinus tracts. Lesions with openings in the external auditory meati were associated with a tract superficial to the facial nerve. Younger children were more likely to have a deep tract with consequent increased risk of facial nerve damage. The fistula may be found anywhere along the anterior border of the sternocleidomastoid muscle.⁶⁰ Solares *et al.*,⁶¹ in their report on ten patients with a mean age of nine years, found seven lesions medial to the facial nerve, two lateral and one between branches of the facial nerve. [**/*]

Neoplasms

In children, the two most common causes of facial paralysis from malignancy are leukaemic infiltration of the temporal bone^{62, 63} and rhabdomyosarcoma of the head and neck.^{64, 65, 66} Levy *et al.*⁶⁷ describe a case of acute mastoiditis and facial paralysis in a five-year-old girl; the diagnosis of leukaemic infiltration of the middle ear cleft

© Hodder Arnold / Scott-Brown 7E

Figure 80.5 Surgery for non-tuberculous mycobacteria (NTM) of the parotid with preservation of the facial nerve. (a, b) Presurgery; (c, d) one week postsurgery.

was made only after surgery and histological examination. Chemotherapy or combined chemo- and radiotherapy are the treatment of choice in known leukaemic patients without symptoms of superimposed infection of the ear or the mastoid process. Surgical management is restricted to cases in which tissue for histological diagnosis is required or drainage of acute infection is needed.

In the Durve *et al.*⁶⁴ series of 14 patients the median age at presentation of rhabdomyosarcoma was 4.5 years with a mean time of onset of symptoms to diagnosis of 21 weeks. Symptoms mimicked those of chronic otitis media, delaying diagnosis. Histological subtype was embryonal in 13 patients and alveolar in 1. All patients underwent multimodality treatment; the five-year disease-free survival rate was 81 percent. Facial paralysis was the most common regional post-treatment morbidity (8 of 14).

The presence of facial paralysis and lymphadenopathy or a mass with aural discharge, hearing loss and aural polyp should prompt urgent investigation and biopsy.

Benign neoplasm of the facial nerve is very rare in children. Facial paralysis from an intracranial neoplasm is uncommon. [**/*]

IDIOPATHIC

Bell's palsy

This is the most common cause of facial paralysis during childhood (42 percent).² It is an acute, unilateral, lower motor neurone facial paralysis diagnosed by exclusion. It is essential that otoscopy is normal, that there is no middle ear infection and the hearing is not impaired. There is a body of opinion that attributes Bell's palsy to infection by herpes virus although the evidence for this is inconclusive. The hypothesis is a reactivation of latent herpes simplex virus within the geniculate ganglion. There is a family history of Bell's palsy in a small number of patients and occasionally a viral prodrome. Steroids are sometimes advocated in the acute stage but the evidence supporting their use is equivocal. The Medical Research Council All Scotland Bell's Palsy randomized double-blind trial (in progress) may answer some of the questions related to the use of steroid and antiviral medication. However, this study is restricted to adult patients with Bell's palsy. Facial paralysis in children is considered to have a good prognosis (90 percent recovery) regardless of treatment. Steroid administration is not recommended.⁶⁸ [**] [Grade C]

Melkersson-Rosenthal syndrome

Episodes of facial paralysis begin in early childhood or adolescence, predominately in the second decade of life. There is swelling of the lips, palatal mucosa and face, and the tongue is fissured. The facial weakness usually takes a recurring course and is seen in 20 percent of cases. A conservative approach is usually recommended.⁶⁹ A preliminary report on the benefit of facial nerve decompression for recurrent facial paralysis in Melkersson-Rosenthal syndrome has recently been further substantiated.^{70, 71, 72}

Wegener's granulomatosis

This is a systemic disease characterized by the classical triad of vasculitis, necrosis and granulomatous inflammation, usually of the upper and lower respiratory tract and the kidneys. Primary otological presentation occurs in 20–25 percent of patients⁷³ and this includes facial paralysis.⁷⁴ A high index of suspicion, erythrocyte sedimentation rate, circulating antineutrophil cytoplasmic antibody and histopathology help diagnose this condition. Combination therapy with corticosteroids and cyclophosphamide is given and co-trimoxazole may be used in the long term to reduce remissions.⁷⁵

Hypertension

Hypertension is a rare cause of facial paralysis in children. Misdiagnosis may lead to serious consequences, as

reported by Aynaci and Sen.⁷⁶ in a case of a hypertensive child with facial paralysis. Bell's palsy was suspected and steroids were given resulting in hypertensive pontine haemorrhage. Recurrent alternating facial paralyses have been reported in a child with hypertension. Antihypertensive treatment and control lead to cessation of further relapse.⁷⁷ [**/*] [Grade C]

KEY POINTS

- The most common cause of facial paralysis in children is Bell's palsy.
- Knowledge of the embryology and developmental anatomy of the facial nerve allows for a clear understanding of the various anomalies and clinical presentations of disorders of the facial nerve.
- There are important anatomical differences between the topography of the facial nerve in adults and children.
- These anatomical differences and the confined surgical space can make tympanomastoid surgery and surgery of the parotid region in children particularly challenging. Surgeons must be extra vigilant to avoid iatrogenic facial palsy.

Best clinical practice

- ✓ MRI is the only imaging modality that demonstrates the facial nerve comprehensively from the pons to the parotid gland; with gadolinium enhancement it is capable of showing inflammatory changes. [Grade C/D]
- ✓ Electroneurography is a useful adjunct to clinical findings in predicting recovery from facial nerve palsy. [Grade C/D]
- ✓ In facial palsy secondary to acute otitis media, optimum management is wide myringotomy and systemic antibiotics. [Grade C/D]
- ✓ Congenital and acquired facial paralysis in the neonate can be differentiated on the basis of examination, supplemented as required, by electrophysiologic investigations. [Grade C/D]
- ✓ Consider facial nerve monitoring during parotid and tympanomastoid surgery, particularly in children with a high incidence of anatomical abnormalities of the facial nerve, e.g. Down syndrome, craniofacial anomalies. [Grade D]
- ✓ Retrograde dissection of the marginal mandibular branch of the facial nerve to find the trunk is particularly unreliable in children. [Grade D]

Deficiencies in current knowledge and areas for future research

- The treatment for facial paralysis remains largely empirical; randomized controlled trials may help answer some of the questions. In view of the small number of cases and the generally good prognosis, a multicentred trial with a sufficiently large number of cases is required.
- The currently available monitoring systems for facial nerve function during surgery lack total reliability and are limited in scope. More sophisticated systems including stealth technology offer the prospect of reduced iatrogenic damage and more precise surgery in areas where the facial nerve is at risk.

Management of epistaxis in the child with an associated medical condition	1067		

SEARCH STRATEGY

The opinions in this chapter are supported by searches of the guidelines databases on www.nelh.co.uk; the Cochrane Library; TRIP database; PubMed limited to randomized controlled trials, human, children 0–18 years; and BestBETS (Best Evidence Topics) using the key words epistaxis and nosebleeds.

INTRODUCTION

Epistaxis (nosebleed) is a common and usually innocuous event in childhood. The condition is a significant nuisance and has an important adverse impact on quality of life for children and their parents. Children are especially susceptible to nosebleeds due to the extensive vascular supply to the nasal mucosa and the frequency with which they develop upper respiratory tract infections.¹ Most cases can be satisfactorily managed using first aid measures by parents or carers. Primary care clinicians are best placed to advise and treat children with nosebleeds and only those with severe acute bleeding, frequent recurrence or a suspected unusual aetiology come to the attention of the otolaryngologist.

variation with a higher prevalence in the winter months, perhaps due to the greater frequency of upper respiratory tract infections or to the drying effect on inspired air of modern central heating systems.⁴ The great majority of children with nosebleeds are otherwise healthy and it is unusual for serious systemic disease to present in this way. Recurrent epistaxis is one of the most common reasons for referral to a paediatric ENT clinic in the UK, reflecting the impact the condition has on quality of life for the child and the family. Bleeds are unpredictable; they cause anxiety and distress, staining of garments and bedclothes, and often concern that there is an underlying medical disorder.

PREVALENCE AND EFFECTS

Everyday experience suggests that epistaxis is common, but epidemiological studies are sparse. It is more common in children with upper respiratory tract allergies.² It is rare in children younger than two. Peak prevalence is in the three to eight years age group.³ There is a seasonal

AETIOLOGY

As in adults, the most common site of origin of childhood nosebleeds is the anterior part of the nasal septum. This part of the nasal mucosa is thin and is exposed to dry air currents during the respiratory cycle.⁴

In contrast with the situation in the adult where the bleeding usually comes from Little's area where there is a dense arterial anastomosis (see Chapter 104, Anatomy of

the nose and paranasal sinuses), often the source in children is the mucosa over a prominent retrocolumellar vein or varix.

Common aetiological associations include infection, digital trauma from repeated nose picking and upper respiratory tract allergy, a nasal foreign body or a deviated nasal septum. Most cases are idiopathic. The mechanism is thought to be drying of the nasal mucosa due to passing air currents such that an area of excoriation or crusting develops and the friable vessels in the nasal lining break down (Figure 81.1). This may explain why the anterior nares is so much more often implicated as inspired air is more thoroughly humidified by the time it reaches the posterior nares.

There are some rare documented causes of nosebleeds in children and it is important to bear these in mind, particularly in recurrent cases with severe recalcitrant bleeds or in an unusual clinical presentation. These are detailed in Table 81.1.

ASSESSMENT AND MANAGEMENT

The acute bleed

Simple measures, such as pinching the nares and ensuring that the child keeps her head forward, are usually sufficient to deal with an acute bleed. If the bleeding is persistent, it is important to reassure the child and the

parent that the condition is benign. Sit the child up in an examining chair and use a good light source or in the case of a very young or frightened child the nose can be examined while the child is sitting on the parent's knee. A good view of the nasal cavities can be obtained by elevating the tip of the nose using the examiner's thumb and using a conventional head mirror before considering a nasal speculum or an endoscope. Primary care clinicians and accident and emergency doctors should be encouraged to develop the skill of examining the nares in a child using an auriscope with a good-sized speculum introduced into the nose as an excellent view can be obtained in this way with minimum distress to the child (see Chapter 63, The paediatric consultation). If there are clots, the child can be asked to blow his/her nose to remove them and in a cooperative child gentle low pressure suction can be used to further clear the nose. If the bleeding site is apparent and the bleeding is not too profuse, it may be possible to cauterize the source using a silver nitrate stick. If using an anaesthetic/decongestant agent, cophenalcaine™ can be applied directly using a cotton wool bud as the child will find this less distressing than a spray. In the fractious child, local anaesthesia can often compound the child's anxiety and for a simple cautery it is best to explain to the child that it may sting a little, (s)he can tell you if (s)he finds it uncomfortable and you will then stop.

If the bleeding is profuse and uncontrollable, resuscitation may be required and it may be necessary to insert a nasal pack or balloon. Children rarely tolerate nasal packing – or balloon tamponade – well. If anterior packing is unsuccessful a post-nasal pack may be considered but this is a major undertaking in a child and will usually require general anaesthesia for insertion – and often for removal – ideally in a high-dependency or intensive care unit with sedation when the pack is in situ.

Recurrent epistaxis

ASSESSMENT

It is important to take a careful history. Enquire if there are any precipitating features, if the child has a background of allergy, if the child is using any medication and

Figure 81.1 Nasal vestibulitis.

Table 81.1 Causes of epistaxis

Common	Less common
Idiopathic: septal arteries, i.e. Little's area; prominent septal veins retrocolumellar vein	Local: septal deformity; tumours; vascular abnormalities
Infection	Systemic: Coagulopathies, primary or secondary; hereditary haemorrhagic telangiectasia
Trauma: nose picking; surgery; septal perforation	
Vestibulitis: Includes foreign body	
Nasal allergy	

enquire which side the bleeding commonly arises from. It is important to thoroughly examine the nasal cavity as detailed above. If the history is of recurrent self-limiting epistaxis in an otherwise healthy child in whom clinical examination is normal or the only findings are of prominent vessels in the typical 'bleeding sites', i.e. Little's area or a retrocolumellar vein, investigations are not routinely required.

Although epistaxis is usually idiopathic, it is prudent to be alert to some of the unusual pathologies which can present this way. Investigations, if needed, must be tailored to the clinical findings.

If there is clinical evidence of allergic rhinitis, such as nasal obstruction, rhinorrhoea, sneezing or the appearance of hyperaemic oedematous nasal mucosa, this may require investigation and management in its own right (see Chapter 83, Paediatric rhinosinusitis).

Enquire about the use of nasal sprays as intranasal steroid sprays can cause localized nasal mucosal trauma often in the region of the anterior end of the inferior turbinate which can give rise to epistaxis.⁵

A concomitant vestibulitis should raise the suspicion of a retained nasal foreign body (Figure 81.1).

Epistaxis alone does not require coagulation screening but if there is evidence of bleeding from other sites, easy bruising or a family history of bleeding, investigations should include full blood count and coagulation screen. Idiopathic thrombocytopenic purpura (ITPP) may present as epistaxis. If a coagulopathy, primary or secondary, is to be excluded it is wise to seek advice from a paediatric haematology colleague as many conditions – such as Von Willebrand's disease – are not easily tested for using conventional coagulation screening.⁶

Nosebleeds in infants and the newborn are especially uncommon. As meningococles and encephalococles may present in this way, careful examination including thorough endoscopy and imaging may be required (see Chapter 82, Nasal obstruction in children).

Examination under anaesthesia may be needed in a very young or fractious child in whom clinical examination is difficult and will certainly be needed for biopsy if a tumour is suspected. Intranasal biopsies in children should only be undertaken with extreme care and having excluded conditions, such as meningocoele, vascular abnormalities and angiofibroma by careful imaging in consultation with a paediatric radiologist and under the supervision of a paediatric otolaryngologist.

Although angiofibroma is uncommon, epistaxis is the most frequent mode of presentation and vigilance is especially important in adolescent boys in whom thorough examination of the nasopharynx is mandatory. This is now best carried out using a nasendoscope. Urgent imaging including MR scanning must be arranged in consultation with a radiologist (see Chapter 102, Imaging in paediatric ENT).

Nasal parasitosis is uncommon in the UK, but in areas where parasites are endemic they may be implicated in

childhood epistaxis (see Chapter 115, Specific chronic infections).

Nasal mycoses may need to be considered, particularly in immunocompromised children, such as those receiving chemotherapy (see Chapter 114, Fungal rhinosinusitis).

Rhabdomyosarcoma can also present with epistaxis (Figure 81.2), although there are usually other signs of an expanding intranasal mass such as cranioopathies or Eustachian tubal dysfunction (see Chapter 98, Tumours of the head and neck in childhood).

Vascular abnormalities such as arteriovenous malformations and haemangiomas are rare causes of childhood epistaxis but may, if suspected, dictate the need for careful imaging, ideally in consultation with a paediatric radiologist.⁷

CONTROVERSIES IN MANAGEMENT

Commonly used methods for the management of recurrent epistaxis in children are the prophylactic application of petroleum jelly to the nasal vestibule and septum, the use of topical antiseptic creams, and cautery of Little's area or the retrocolumellar veins. If the bleeding is persistently from one side, often you will find either a leash of vessels around Little's area on the affected side or a prominent retrocolumellar vein. Both of these are easy to deal with by cautery. Cautery nowadays is most often undertaken using a silver nitrate impregnated stick (Figure 81.3). The use of strong caustic agents,

© Hodder Arnold / Scott-Brown 7E

Figure 81.2 A nasal mass (for example, rhabdomyosarcoma) may present with epistaxis.

© Hodder Arnold / Scott-Brown 7E

Figure 81.3 Silver nitrate cautery.

such as trichloroacetic acid, which can burn skin and adjacent structures, is to be deprecated.

Petroleum jelly is thought to be effective because it forms a water-resistant film over the affected area of mucosa. In addition, antiseptic creams are thought to sterilize localized infection in the region of the vestibule and the nasal septum.

The evidential base for management of recurrent nosebleeds in children is poor.^{8,9} Commonly used therapeutic options which have been evaluated are:

- expectant treatment, i.e. first aid management of acute bleeds as they arise;
- use of an oil-based antiseptic cream;
- application of petroleum jelly;
- nasal cautery using silver nitrate;
- electrocautery ('hot wire') to the suspected bleeding point.

Less common interventions include laser therapy, limited septoplasty, local application of tranexamic acid gel¹⁰ and fibrin glue,¹¹ endoscopic treatment of offending vessels by diathermy or ligation and in recalcitrant cases embolization under the supervision of a radiologist¹² (see Chapter 126, Epistaxis, for a full discussion on treatment options for epistaxis in adults).

As the majority of children with recurrent nosebleeds do not come to the attention of an otolaryngologist, 'expectant' treatment is the most frequently used option. Outcomes following treatment are difficult to standardize and evaluate.

There are few data on the long-term history of children with recurrent epistaxis, but anecdotal evidence suggests that most children spontaneously improve.

Creams and petroleum jelly are widely recommended by primary care clinicians and otolaryngologists. Ruddy *et al.*¹³ conducted a prospective randomized controlled trial (PRCT) comparing antiseptic cream alone with nasal cautery using recurrence as an outcome measure and found no difference. Murthy *et al.*,¹⁴ in a PCRT, compared the use of silver nitrate cautery alone with silver nitrate cautery and adjunctive treatment with an antiseptic cream. Using self-reported recurrent epistaxis rate as an outcome measure, he found no difference between the groups. Kubba *et al.*¹⁵ compared chlorhexidine cream with no treatment and found a significant reduction in bleeding in the treatment group. In a small PCRT of children referred to an otolaryngology service and using as an outcome measure the frequency of reported bleeds in the four weeks prior to consultation with an otolaryngologist, Loughran *et al.*¹⁶ compared the efficacy of vaseline jelly applied twice daily by the parent to the nasal mucosa with no treatment. He found no difference in the groups.

All of the above studies were dogged by low study power, incomplete follow up and variable outcome measures.

Furthermore, nasal carrier cream delivery is difficult to standardize and depends on parental cooperation and compliance. Nasal cautery is a surgical procedure requiring some training and skill (Figure 81.3), but it is often delegated to surgeons in training and to nursing personnel with varying degrees of supervision. Follow-up arrangements vary greatly and 'blind' cautery of the nasal septum is often advised even if there is no visible source for bleeding. It seems reasonable to regard the success or otherwise of nasal cautery as operator-dependent. The anecdotal experience of otolaryngologists is that judicious cautery of an obvious offending vessel is worthwhile and is associated with reduced recurrence.

Extensive cautery may be complicated by the development of a nasal septal perforation (Figure 81.4). Traditional advice has been that this is more likely if adjacent areas on both sides of the nasal septum are cauterized at one sitting. Although there is no direct evidence for this, it seems prudent to defer cautery of the second side if needed, until the result of cautery on one side can be evaluated over a period of four to six weeks.

Tradition once dictated that children who did not tolerate silver nitrate cautery, or who had recurrent bleeding following outpatient cautery, were offered electrocautery. This usually requires general anaesthesia. The evidence that this is in any way better than silver nitrate is weak. Toner and Walby,¹⁷ in a PRCT, compared electrocautery with cautery with silver nitrate and adjunctive use of an antiseptic cream and found no difference in the two groups using the number with recurrent bleeding in each group as an outcome measure.

Makura *et al.* conducted a prospective audit and looked at tolerance to outpatient cautery, which he found was as high as 98 percent, but the application of silver nitrate to the mucosa is painful.^{9,18}

Based on the evidence presented, there is no certainty that nasal cautery is better than no active treatment, but if the child has been referred to a paediatric ENT clinic and has had treatment under the supervision of a primary care team, usually consisting of application of creams or jelly,

© Hodder Arnold / Scott-Brown 7E

Figure 81.4 Nasal septal perforation.

it seems reasonable if there is a visible prominent nasal vessel to cauterize it. The morbidity is low and anecdotal evidence suggests that it is worthwhile. The evidence from randomized controlled trials comparing petroleum jelly with antiseptic creams suggest that there is little to choose between them on clinical grounds and as the jelly is cheaper and more widely available it should be considered first. [**] The most widely used antiseptic cream is Naseptin™ – a combination of chlorhexidine and neomycin. As it contains peanut oil it must not be used in suspected peanut allergy.

Less commonly considered interventions, such as laser treatment, fibrin glue, septoplasty and endoscopic diathermy, are only applicable on an individual case basis and do not currently have a strong evidential base. [*/*]

MANAGEMENT OF EPISTAXIS IN THE CHILD WITH AN ASSOCIATED MEDICAL CONDITION

Children with upper respiratory tract allergy should be managed in the first instance with treatment appropriate to the primary allergy, i.e. intranasal steroids and antihistamines. Paradoxically, one of the troublesome side effects of intranasal steroid treatment is nosebleeds, thought to be due to the effect of the propellant in nasal steroid delivery systems on the mucosa. This is usually mild and self-limiting (see Chapter 83, Paediatric rhinosinusitis).

Septal deviation can cause epistaxis particularly if there is a prominent septal spur. This can subject an area of nasal mucosa to dry cold air currents which can cause mucosal excoriation. A limited septoplasty may be curative but with the usual caveats that apply to nasal septal surgery in children (see Chapter 123, The septum).

Although the condition is congenital, hereditary haemorrhagic telangiectasia (HHT) is rarely diagnosed in children. Most adult patients will recollect episodes of troublesome bleeding in adolescence (see Chapter 126, Epistaxis). If there is a family history, or if there are telangiectasia on the nasal or buccal mucosa, genetic testing should be considered. Treatment is directed at managing acute bleeds and the gamut of treatment options available in adults may be considered, but the condition is rarely florid in childhood or adolescence. Nasal cautery in these children should be considered with extreme care as nasal septal perforation, and indeed collapse, may complicate multiple cauteries.

Children with advanced malignant disease may have profuse and uncontrollable nosebleeds. As treatment strategies and survival in paediatric oncology improves, otolaryngologists are increasingly asked to help in the management of these children. Thrombocytopenia is a common factor. Severe bleeding can cause great distress and may be life threatening. These children are managed in liaison with a paediatric oncology team or a palliative care clinician. They may require nasal packing, repeated

transfusion and platelet therapy. Exceptionally, balloon tamponade or a postnasal pack can be considered. Management of the child's nosebleeds can be an important element of palliative care. Nasal tampons are gentler and easier to insert than BIPP™ packs.

CLINICAL GUIDELINES

Based on the above, the following clinical guidelines seem appropriate for recurrent epistaxis in childhood where there is no systemic disease and no anatomical aetiology other than a plexus in Little's area or a varix in the retrocollumellar area.

- Expectant treatment may be recommended in mild cases. [Grade C/D]
- Petroleum jelly is associated with little or no morbidity and is a reasonable primary care treatment. [Grade C]
- A nasal barrier cream offers limited benefit but morbidity is low and the treatment can be prescribed in primary care. [Grade C]
- If cautery is considered, silver nitrate is the optimum method. [Grade B]
- Nasal cautery is a procedure requiring skill, training and the evaluation of outcome. Haphazard application of caustic agents to the child's nasal mucosa is unwise. [Grade D]
- Electrocautery should rarely be considered. [Grade C/D]
- Very few children require general anaesthesia. [Grade C/D]
- There are no studies comparing antiseptic cream with petroleum jelly, but it seems reasonable to recommend antiseptic preparations in the presence of a concomitant vestibulitis, otherwise cost and ease of application should dictate the choice. [Grade C]
- Laser therapy, fibrin glue and septoplasty have essentially not been evaluated and can only be considered on an individual basis. [Grade D]
- Neither systemic nor local tranexamic acid has any place in the treatment of childhood epistaxis. [Grade C]
- The innovative techniques for epistaxis which have been pioneered by adult rhinologists, such as endoscopic ligation of the sphenopalatine artery, have not yet been widely applied in children but may have a limited role (see Chapter 126, Epistaxis).

KEY POINTS

- Epistaxis in children is extremely common and usually innocuous.

- Most acute bleeds settle with simple therapeutic interventions that parents and carers can administer at home.
- Investigations are rarely required.
- Spontaneous resolution is common for children with recurrent epistaxis.

Best clinical practice

- ✓ Other than careful rhinoscopy, no formal investigations are required for children with recurrent epistaxis who are otherwise in good health and where clinical history and findings on examination are unremarkable.
- ✓ Indications for referral to an otolaryngologist include:
 - troublesome recurrent epistaxis where treatment with nasal barrier creams has been unsuccessful;
 - associated nasal discharge;
 - children with a known or suspected haematological disorder;
 - a short history of severe bleeds;
 - persistent unilateral symptoms;
 - associated vestibulitis;
 - parental concern;
 - systemic disease or upset.
- ✓ Adolescent boys with unexplained epistaxis need urgent referral.
- ✓ Nasal cautery using silver nitrate in the hands of an appropriately trained clinician is an innocuous well-tolerated procedure with little morbidity and should be undertaken where there is an evident blood vessel.
- ✓ Naseptin creamTM contains peanut oil and must not be used in children with suspected peanut allergy.

Deficiencies in current knowledge and areas for future research

- The role of silver nitrate seems unlikely to be validated by randomized controlled trials as the technique is operator dependent.
- There are no good studies looking at the effect of epistaxis on quality of life and at the effect of intervention on quality of life indices.
- If we are to conduct large population studies on the natural history of epistaxis and the effect of intervention, these will need to be primary-care centred as most children with epistaxis do not come to the attention of an otolaryngologist.
- Optimum treatment of nosebleeds in systemic malignant diseases needs to be streamlined and improved.

SEARCH STRATEGY

The evidence-base for this chapter is supported by a Medline search using the key words nasal obstruction and children and focusing on a variety of key words appropriate to the individual topics. These include all the subheadings listed below (e.g. choanal atresia, pyriform aperture stenosis, etc.). The Cochrane database and the National Electronic Library for Health for ENT were also consulted.

INTRODUCTION

The causes of nasal obstruction in children are numerous and diverse, but the symptoms are essentially similar. Stertor, mouth breathing, feeding problems, sleep disturbance and rhinorrhoea are all frequently reported. Concern should be heightened if there is failure to thrive, significant nocturnal obstruction, intermittent cyanosis or apnoea.

The severity of the problem will depend on the degree of the blockage and the size of the child. A clinical history will ascertain whether the problem is uni- or bilateral, complete or partial, intermittent or constant, acute or chronic. It is useful to know whether the symptoms were with the child from birth or have developed subsequently and whether the onset has been gradual or sudden. Newborns are generally obligate nasal breathers for the first few months of life and so nasal obstruction in this group can present as an acute respiratory emergency. The extent of the problem will alter related to the child's ability to breathe orally, which corresponds to their level of maturity and neurological development. An oral airway is often enough to relieve distress until definitive treatment can be undertaken.

Examination is essential. It can be particularly helpful if the child will permit the use of flexible or rigid endoscopy. Imaging via computed tomography (CT) and magnetic resonance imaging (MRI) has been shown to be of great value in delineating both nasal and post-nasal lesions.

Tables 82.1, 82.2 and 82.3 outline the variety of causes of nasal obstruction in children. This chapter aims to review those conditions not covered elsewhere in this book.

CONGENITAL DISORDERS

Skeletal anomalies

CHOANAL ATRESIA

In this rare condition (incidence 1 in 7000 live births), there is complete obstruction of the posterior nasal openings on one or both sides (Figure 82.1). The blockage has been thought to be either bony or membranous in origin. In reality, a mixed picture is usually seen (70 percent of cases) with the remainder

Table 82.1 Congenital causes of nasal obstruction in children.

Anatomical/skeletal abnormalities	Nasal cysts	Nasal masses
Choanal atresia	Dermoid	Meningo-/encephalocele
Pyriform aperture stenosis	Nasoalveolar	Glioma
Nasal agenesis	Nasolacrimal	Hamartoma
Craniosynostosis syndromes	Dentigerous	Chordoma

being purely bony. It is believed to be secondary to persistence of the nasobuccal membrane (see Chapter 65, Head and neck embryology).

Bilateral choanal atresia will present as an acute respiratory emergency at birth as newborns are obligate nasal breathers. The classical picture of cyclical cyanosis (blue spells relieved by crying) is seen. Placement of an appropriately sized oral airway usually resolves the distress. It may be helpful to place a metal spatula just below the child's external nasal aperture; misting excludes a diagnosis of choanal atresia. The inability to pass nasal catheters suggests the diagnosis which can be confirmed by flexible endoscopy or CT scanning (with suction clearance of the nose and the application of 0.5 percent ephedrine drops 30 minutes previously) (Figure 82.2). If an oral airway is well tolerated, transfer is often possible without endotracheal intubation, though this may be required in certain cases.

Choanal atresia may be an isolated anomaly or one feature of a number of associated congenital anomalies, e.g. CHARGE association (coloboma, heart defects, atresia choanae, retardation of growth, genital

© Hodder Arnold / Scott-Brown 7E

Figure 82.1 Unilateral choanal atresia as viewed from the nasopharynx with a 120° endoscope. A sound is perforating the membrane.

anomalies and ear abnormalities). These associated anomalies should be excluded in a baby with choanal atresia. Minimum investigations in addition to the nasal CT scan are cardiac echo, renal ultrasound scan and an ophthalmology and audiology review.

Unilateral problems often come to light in an older child with a persistent profuse one-sided nasal discharge in whom there is no history of foreign body insertion.

Numerous techniques have been described for the correction of choanal atresia with little direct comparisons made. Outcomes are themselves hard to define objectively. Most studies rely on clinical judgements made by the surgeon as to the size of the nasal airway and

Figure 82.2 CT scan (axial view) to illustrate the expansion of the posterior vomer and medial maxillary walls of the nasopharynx in choanal atresia (arrowed).

opinion from the patient and their family as to whether they are 'asymptomatic'. The number of surgeries required and time taken to obtain a satisfactory outcome are also used to make comparison. **Rx**

Transpalatal and transnasal surgery have been shown to have similar outcomes.¹ **Endoscopic transnasal** approaches have also been successfully reported.² The technique described in three papers from Great Ormond Street Hospital, London^{3,4,5} represents the largest reported experience at 161 patients and involves a transnasal repair under direct vision. A 120° endoscope is placed in the mouth and positioned in the nasopharynx behind the soft palate. The atretic plate is perforated initially with a sound and currently is removed with the specifically designed microdebrider attachment (previously a diamond paste burr was used). Bilateral nasal stents are fashioned from two Ivory Portex™ endotracheal tubes cut to length, with the bevelled end of each sitting in the nasopharynx orientated towards the septum. The philtrum is protected by either a small length of size 12 suction catheter cut to act as a bridging piece or a further small piece of endotracheal tube (**Figure 82.3**). The stents are secured by a circumseptal '0' prolene suture and are left *in situ* for six weeks. Others use a single tube as a stent which has a window cut in the middle to allow access for the securing suture and avoids the need for a bridging piece (**Figure 82.4**). Scrupulous stent care is vital to prevent obstruction or damage to the nasal soft tissues. Some authors do not favour stenting in unilateral or even bilateral cases. It is suggested that removal of the posterior aspect of the vomer along with the atretic plate and the use of powered instruments have made stents unnecessary. Authors who support this view do stress the need for early repeat examination for removal of granulations and dilatation as required.^{2,6}

Given the limitations in the definition of outcome as described above, **success rates** have been shown to be

© Hodder Arnold / Scott-Brown 7E

Figure 82.3 Bilateral nasal stents with an endotracheal tube bridging piece.

© Hodder Arnold / Scott-Brown 7E

Figure 82.4 Bilateral nasal stents without a bridging piece.

similar over the past 20 years with the three Great Ormond Street Hospital (GOSH) papers showing rates of between 68 and 80 percent for bilateral and 82–93 percent for unilateral atresia. The length of time for follow-up has been variable, but is only quoted in months in the GOSH papers. A group of 78 children from the Philadelphia Children's Hospital were followed up for 35 months on average with similar results.⁷

The role of mitomycin C (MMC) in the treatment of choanal atresia is still being clarified. MMC is an anti-neoplastic agent which acts to **inhibit fibroblasts and angiogenesis** and so reduces granulation tissue and fibrosis. It is suggested that its use at the time of stent removal and at subsequent dilatations improves outcome. A variety of doses and protocols have been described and some benefit has been reported.⁸ The KTP laser has also been shown to be helpful in the treatment of granulation tissue which develops postoperatively.¹

PYRIFORM APERTURE STENOSIS

This abnormality, first described in 1988, arises due to bony overgrowth of the nasal process of the maxilla

Figure 82.5 CT scan (axial view) of bilateral pyriform aperture stenosis. Note the single central incisor.

(Figure 82.5).⁹ The pyriform aperture is the narrowest part of the nasal airway and so even minimal reduction in diameter here can cause significant problems. Symptoms similar to bilateral choanal atresia occur and epiphora is also often seen secondary to bony involvement of the nasolacrimal ducts. Endoscopy is prevented by the bony obstruction at the vestibule. CT scan confirms the diagnosis and shows the single central incisor which exists in some affected individuals. In this subgroup with a 'mega-incisor', there is a suggested association with holoprosencephaly, a rare congenital condition in which the developing forebrain fails to divide appropriately to form the cerebral hemispheres, diencephalon and optic and olfactory bulbs. These patients should undergo further evaluation for central nervous system (CNS) defects and particularly the hypothalamic–pituitary–thyroid axis.

Conservative treatment in the form of nasal topical medication is often sufficient, but if there is severe obstruction; respiratory distress or failure to thrive, surgical intervention is necessary. The approach can be transnasal with an alar-releasing incision or sublabial. The mucosa is lifted and the abnormal bone drilled away. Nasal stents are then placed for several weeks.

NASAL AGENESIS

Complete arhinia is very rare but can occur either in isolation or as part of a syndrome. It originates at the fifth week *in utero* when the nasal placode fails to canalize to form the nasal passages. Presentation at birth with acute respiratory distress is usual (neonates are obligate nasal breathers), though problems sometimes do not arise until feeding is attempted. Management is with an oral airway and tube feeding prior to definitive treatment.

Congenital nasal cysts

Congenital cysts, as described in Table 82.1, can either obstruct the nose or cause discharge from an associated sinus tract.

DERMOID CYST

Dermoid cysts (Figure 82.6) derive from ectoderm and mesoderm and can contain all the structures of normal skin. Nasal lesions account for between 1 and 3 percent of all dermoids and are the most common midline nasal mass. There is debate as to their origin. One theory is that they originate from an embryological aberration resulting in inadequate closure of the fonticulus frontalis, which then allows dermal tissue to extend between the nasal bones and cartilage. Dura can also extend down through this area. Another suggestion is that there is a persistence of residual dura in the prenasal space. The prenasal space runs in the midline between the developing nasal bone and underlying cartilage from the brain to the nasal tip. The misplaced dura is believed to form a contact with the skin and then it retracts to result in a sinus, in which a cyst can then develop.

Dermoids usually present as a slowly growing cystic midline mass over the nasal dorsum. An associated pit can often be seen in any position from the nasal tip to the glabella, hair may be present at its opening. Infection of a dermoid can result in abscess formation requiring drainage. Early surgical excision is recommended to prevent either this complication or further expansion of the cyst with associated destruction of local tissue.

Preoperative assessment for intracranial extension is essential. CT is helpful for bony anatomy, while MRI delineates a CNS connection.

Figure 82.6 Midline nasal sinus associated with an underlying dermoid cyst.

Surgical approaches depend on the position of the cyst. If it is in the lower half of the nose, an open rhinoplasty procedure is an excellent way of removing pathology and obtaining a good cosmetic result. Cysts higher up the nose may need direct excision via an elliptical incision. Extension of the sinus tract deep to the nasal bones usually necessitates a medial osteotomy to permit adequate exposure for removal. Some find a lateral rhinotomy a useful approach to expose the septum and so allow complete removal of the cyst and associated tract. Any punctum in the skin will require local excision.

Careful consideration is required for intracranial extension. If this occurs, a combined intracranial/extracranial procedure is recommended. If it is only suspected, it is appropriate to approach the lesion via the nose first and only proceed with the craniotomy if absolutely required.¹⁰ [**]

NASOLACRIMAL DUCT CYSTS

The nasolacrimal duct system should canalize *in utero* from a superior to inferior direction, but at birth the lower end not infrequently can remain closed. Thirty percent of babies are born with nasolacrimal duct

blockage. If there is no lumen at both ends of the system, fluid builds up resulting in a cyst. These lesions cause epiphora and nasal obstruction sometimes leading to feeding difficulties and respiratory distress. They can be unilateral or bilateral. Eighty-five percent of cases resolve spontaneously by nine months of age.

Diagnosis is made by clinical examination and CT. On the latter, a dilated nasolacrimal duct, an intranasal cyst and cystic dilation of the lacrimal sac are seen. If surgical removal is required, endonasal marsupialization under endoscopic guidance is recommended, though endonasal ablation with a carbon dioxide laser has been described.¹¹ [**] Ophthalmology input is helpful as intraoperative nasolacrimal probing and stenting may be needed.

THORNWALDT'S CYST

The pharyngeal recess or bursa sits in the midline of the posterior wall of the nasopharynx. It ends next to the adenoids and is lined by the pharyngeal mucous membrane. Cystic transformation of this recess was first described by Thornwaldt in 1885 and so bears his name. Inflammation of this lesion causes nasal obstruction, occipital pain, fullness in the ears and discharge. Endoscopic examination will confirm the diagnosis. Imaging by CT and MRI will show any adhesion to the cervical vertebrae. Incision or excision of the cyst have been described, while total clearance would involve a transpalatal approach.

NASOALVEOLAR CYSTS

These are rare, nonodontogenic, soft tissue lesions arising from the incisive canal during the development of the maxilla. They present lateral to the midline at the alar base and can cause asymmetrical alar flare. Excision is usually via a sublabial approach.

DENTIGEROUS CYSTS

These present in the floor of the nose or maxillary sinus and have a dental origin. Endoscopic marsupialization or removal via the nose is usually satisfactory.

MUCOUS CYSTS

Mucous cysts have been described anywhere in the nose, but appear to be more common in the floor. They may be congenital, but are more usually seen as a complication of rhinoplasty. Endoscopic and open approaches are used, depending on the position of the lesion.

Congenital nasal masses

A congenital nasal mass can consist of ectopic intracranial tissue. The structures may have prolapsed into the nasal cavity and become disconnected, but in many cases an intracranial connection is maintained.

ENCEPHALOCOELE, MENINGOCOELE AND GLIOMA

A nasal encephalomeningocoele represents a herniation of meninges with or without associated brain through bony defects of the calvarium. A meningocoele consists of either meninges alone or with cerebrospinal fluid (CSF) and an encephalocoele contains nervous tissue. Gliomas (**Figure 82.7**) are benign midline masses containing glial cells, fibrous and vascular tissue. Gliomas are similar to encephalocoeles, but have become separated from the intracranial structures. However, 15 percent do remain attached to the brain via a fibrous stalk. Presentation is

Figure 82.7 Broadened nasal dorsum in a child with a glioma.

usually early on as a firm, noncompressible, reddish swelling. If the diagnosis is not obvious, differentiation between these lesions and encephalocoeles can be made in a number of ways. A probe will pass laterally but not medially to an intranasal encephalocoele, while an intranasal glioma can arise from the lateral nasal wall. Furstenberg's test (compression of the internal jugular vein) usually causes an encephalocoele to enlarge, but not a glioma. Imaging (CT/MRI) confirms the nature of the lesion.

If the obstruction is causing significant problems, surgical removal of a glioma is recommended. The approach depends on the size and position of the lesion and can be performed intranasally or via a lateral rhinotomy or external rhinoplasty procedure.¹² Encephalocoeles and meningocoeles that need surgery usually require a combined transnasal and neurosurgical approach.

NASAL HAEMANGIOMA

These are benign lesions which come under the general classification of vascular malformations (**Figure 82.8**). They can occur in the nose either externally or internally, the latter often arising from the turbinates.

Classically, a haemangioma is either absent or flat at birth and then undergoes a period of rapid growth to present as a mass at around six weeks of age. Growth then continues for the first six months of life before gradual involution occurs and the lesion generally disappears by around the age of six years. This natural history supports conservative management if possible. MRI is the recommended mode of imaging if required and it is particularly useful to exclude an intracranial connection. Liaison with a paediatric dermatology team is vital in patient management as their experience with haemangiomas elsewhere gives invaluable expertise. The first-line intervention would be the use of oral steroids, which are of greatest

Figure 82.8 External nasal haemangioma in a 10-week-old girl.

● Hodder Arnold / Scott-Brown 7E

benefit in the rapid growth phase. If rapidly enlarging and encroaching on surrounding structures, e.g. the orbit, a short course of treatment with an anti-proliferative agent, such as methotrexate or vincristine, may be considered under the supervision of a paediatric oncologist.

Surgical treatment may be required, particularly if there are airway or feeding issues. Rarely there can be bleeding, ulceration, platelet consumption, cardiovascular compromise or infection.

MISCELLANEOUS NASAL MASSES

Hamartomas, chordomas, teratomas and craniopharyngiomas are extremely rare causes of nasal obstruction in the child.

ACQUIRED ABNORMALITIES

Osseocartilagenous septal deformity

A number of babies are born with a septal deviation either in isolation or in association with an abnormality of the bony pyramid. It is felt that this problem is either due to intrauterine positioning or to birth trauma (moulding). Closed reduction of the septal deformity with topical anaesthetic in each nostril in the first few days of life has been described by a number of authors and a recent review of long-term follow-up has stressed its importance.¹³ It may be appropriate, however, only when there is a significant problem with airway compromise as others have shown complete resolution of the problem without any intervention.¹⁴

Deformity in older children is usually felt to be due to some form of injury that may have been subtle and unnoticed by either parent or child. There is much debate as to whether septal surgery is appropriate in the growing nose. The main growth centre of the nose is at the septovomerine angle and there is concern that even minor disruption here can lead to significant problems with the final midfacial contour.

Animal studies have shown the development of further septal deviations and poor cartilage regeneration following cartilage resection, crushing and reimplantation.¹⁵ However, a study of anthropometric measurements before and after external septoplasty in 26 children (mean age 9.5 years, with mean follow-up of 3.1 years) showed no deleterious effect of surgery on the development of the nose and midface.¹⁶ Corrective surgery for nasal cartilaginous abnormality in children with cleft lip and palate has been carried out at around seven to eight years of age without affecting midfacial growth.

Generally, if the symptoms are significant, a limited septoplasty with the minimal removal of cartilage is acceptable. Care should be taken not to disrupt the upper lateral cartilages.

Similar concerns have been raised regarding surgery to the bony septum and nasal pyramid. Waiting until at least the early teenage years is felt to be appropriate. Interestingly, though the external rhinoplasty approach has been used for other reasons in very young children no detrimental effects on nasal growth have been reported.

Septal haematoma/abscess

Persistent nasal obstruction following injury should raise concern regarding the possibility of a septal haematoma. These are more common in children than adults, as the former have a thicker and more elastic mucoperichondrium, which often remains intact while the septal vessels below rupture. Pain and fever occur if a septal abscess develops. Both these conditions require drainage to prevent septal perforation.

Foreign bodies

In a small child with unilateral foul discharge, a nasal foreign body must be excluded. If the object has been present for some time, calcareous deposits can form around it resulting in a rhinolith. Care must be taken to act quickly if a battery has been placed in the nose as septal erosion can rapidly occur (see Chapter 92, Foreign bodies in the ear and the aerodigestive tract in children, for further details).

Physiological rhinitis

NEONATAL RHINITIS

Swelling of the nasal mucosa in newborn infants can cause significant airway problems, particularly when feeding, as babies are obligate nasal breathers.

Idiopathic neonatal rhinitis is characterized by mucoid rhinorrhoea with nasal mucosal oedema in the afebrile newborn. This results in stertor, poor feeding and respiratory distress.¹⁷ Structural abnormality, such as choanal atresia or pyriform aperture stenosis, must be excluded before making the diagnosis. Treatment of neonatal rhinitis depends on the severity of symptoms. Nasal bulb suction with saline drops in the first instance is recommended. A short-term course of steroid nose drops would be the next step. This should be closely monitored to avoid the potential side effects from systemic absorption.

Children with infective rhinitis have purulent rhinorrhoea and sometimes associated fever, while allergic rhinitis with sneezing and lacrimation is very unusual in the neonatal period.

It is important to consider chlamydia infection acquired in the birth canal. This usually results in conjunctivitis, but involvement of the nose is seen in

around 25 percent of affected individuals. Presentation is with obstruction, rhinorrhoea and a markedly erythematous nasal mucosa on examination. Swabs are diagnostic and the appropriate antibiotic should be prescribed.

Rarely congenital syphilis (*Treponema pallidum*) can cause nasal symptoms in the newborn. Thin, clear secretions are seen between the second week and third month of life. This progresses to a mucopurulent discharge with significant obstruction and crusting of the nostrils. Antibiotic treatment is required both for symptomatic relief and to prevent chronic infection of the cartilage resulting in a saddle deformity.

PUBERTAL RHINITIS

The symptoms of rhinitis are reported as coinciding with the onset of puberty, often in girls and less so in boys. The aetiology is felt mainly to be due to the rise in blood oestrogen levels that occur at this time with some effect also from increased testosterone levels. Oestrogen is known to increase acetylcholine levels by inhibiting acetylcholinesterase. Acetylcholine is a potent vasodilator produced by parasympathetic nerve endings which pass to the nasal mucosa in the vidian nerve. The net result is swelling of the nasal mucosa with increased nasal secretions.¹⁸

Fibro-osseous disease

This term is used to describe a group of rare disorders, which can affect any bone in the body, including those of the nasal skeleton. They are characterized by the replacement of normal bony architecture with fibroblasts, collagen fibres and a variable amount of mineralized material. Nasal problems are caused by a lesion developing from the upper jaw and spreading out to block the paranasal sinuses and nostrils (Figure 82.9). There may also be significant aesthetic concerns, interruption to the development of the dentition and orbital involvement.

Figure 82.9 CT scan of fibrous dysplasia.

Fibro-osseous disease encompasses fibrous dysplasia (FD), benign fibro-osseous neoplasms (including ossifying fibroma) and reactive dysplastic lesions. However, a precise classification of this group of lesions is still a matter of debate. Fibrous dysplasia and ossifying fibroma can present a nasal obstruction in a young child and differentiating between the two conditions may not always be possible. Fibrous dysplasia has three subtypes: monostotic, which involves one site and accounts for 70 percent of cases; polyostotic, which involves multiple bony sites and a polyostotic form with extraskeletal abnormalities (McCune–Albright syndrome) in which there are café-au-lait spots and multiple endocrinopathies due to autonomous secretion of hormones. A mutation in a stimulatory G protein subunit (G α) has been found in all three subtypes of fibrous dysplasia.

Imaging is helpful in diagnosis. Fibrous dysplasia has diffusely blending margins, unlike the clearly defined ossifying fibroma. Areas within FD will show an opaque appearance (ground-glass effect), be cystic or multiloculated. The thinned overlying bone has reactive periosteal new bone formation.

Fibrous dysplasia will stop growing at skeletal maturity, whereas the progression of ossifying fibroma is uncertain. Complete surgical excision of ossifying fibroma is ideal, but may not always be possible. In fibrous dysplasia, surgery is performed if significant compression of adjacent structures is occurring. Treatment is surgical, but total excision is often not possible. The aim is to preserve function and limit disability. Endoscopic techniques have been described to excise small lesions limited to the nose or paranasal sinuses, but with extensive disease, the midface degloving approach is recommended. Postoperative baseline imaging is required as recurrence rates are high and repeated procedures may be necessary. Radiotherapy is not used because of the risk of sarcomatous change. Spontaneous malignant change has been reported and is more common in the polyostotic form.

KEY POINTS

- Newborn infants are obligate nasal breathers; nasal obstruction can cause significant respiratory compromise.
- Affected infants may develop stertor, mouth breathing, feeding problems, sleep disturbance and rhinorrhoea.
- Immediate relief can be brought about by placement of an oral airway.
- Choanal atresia may occur in isolation, but is often one of a number of associated anomalies.
- A congenital nasal mass can consist of ectopic intracranial tissue.

Best clinical practice

- ✓ Use of an oral airway in neonates with nasal obstruction can facilitate transfer for definitive treatment. [Grade C/D]
- ✓ Minimum additional investigations required in a child with choanal atresia to look for CHARGE association are echocardiography, renal ultrasound and ophthalmology/audiology review. [Grade C/D]
- ✓ Early surgical excision of dermoid cysts is recommended before infection or further expansion occurs. [Grade C/D]
- ✓ Nasal masses may not be as innocuous as they seem; always consider intracranial extension and arrange appropriate imaging. CT is helpful for bony anatomy. MRI may identify a CNS connection. [Grade C/D]
- ✓ Compression of the internal jugular vein (Furstenberg's test) usually causes an encephalocoele, but not a glioma, to enlarge. [Grade C/D]
- ✓ Idiopathic neonatal rhinitis is underdiagnosed and improves with intranasal steroids. [Grade C/D]
- ✓ The external rhinoplasty approach causes minimal cosmetic deformity and is extremely useful in the surgical management of nasal masses. [Grade C/D]
- ✓ Despite the uncertainty about long-term outcomes, septoplasty in children can be undertaken with caution, but only when there are significant symptoms. Cartilage excision should be minimized. [Grade C/D]

Deficiencies in current knowledge and areas for future research

- Multi-centre studies are required to clarify the role of mitomycin C in the treatment of choanal atresia.
- The long-term outcomes of nasal septal surgery in children are still uncertain.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words paediatric rhinosinusitis, complications, sinusitis, upper respiratory tract infections, immune deficiency, reflux, primary ciliary dyskinesia, cystic fibrosis, orbital cellulitis, endoscopic sinus surgery, adenoidectomy and by reference to the Oxford textbook of paediatrics, plus articles already in the authors' bibliographies.

INTRODUCTION AND DEFINITION

'Rhinosinusitis' implies inflammation of the mucus membrane lining the nose and sinuses resulting in two or more of the following symptoms. One to be:

- blockage/congestion or
- nasal discharge (anterior/posterior);
- facial pain/ pressure;
- decrease or loss of smell;

with one or more of the following:

- endoscopic signs of polyps;
- mucopurulent discharge from the middle meatus;
- oedema and mucosal obstruction, primarily in the middle meatus;
- CT mucosal changes in the ostiomeatal complex and/or sinuses.¹

The nature and pattern of inflammation varies between patients from allergic (with eosinophil predominance) to infectious with neutrophil predominance. The pattern may also vary with time and treatment within an

individual. Rhinitis may exist alone, but is frequently accompanied by sinus mucosal changes – rhinosinusitis. The condition may be acute or chronic.

Acute sinusitis lasts under 12 weeks or occurs under six times per year. Bacterial sinusitis complicates 0.2 to 2 percent of viral upper respiratory tract infections.² Five to 13 percent of the general population may have experienced sinusitis during childhood,³ but less than 0.5 percent of those affected are likely to require hospital care.⁴

Recognized factors predisposing to paediatric rhinosinusitis include the following:^{5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21}

- allergy: intermittent and/or persistent;
- innate immune deficiency: primary ciliary dyskinesia, cystic fibrosis;
- acquired immune deficiency: IgA deficiency, IgG subclass deficiency, variable immune deficiency;
- gastroesophageal reflux disorder;
- environmental pollution: malnutrition, hyposplenism, diabetes mellitus, immune suppression, biochemical abnormalities.

EPIDEMIOLOGY

All children suffer from rhinitis/rhinosinusitis at some time. The average child has six to eight viral colds per year – more if in day care. The prevalence of allergic rhinitis has recently been investigated by the International Study of Asthma and Allergies in Childhood (ISAAC) in six to seven and thirteen to fourteen year olds. As with asthma, paediatric allergic rhinitis is more common in westernized societies, possibly related to lack of infection and to dietary factors.²² Paediatric rhinosinusitis is usually a self-limiting disorder.^{23, 24, 25} Surgery is rarely needed, but a long-term medical approach may be required where there are underlying predisposing factors such as allergic rhinitis or immune defects.

ALLERGIC RHINITIS

This can be classified according to the Allergic Rhinitis and its Impact on Asthma (ARIA) document²⁶ as intermittent or persistent depending on whether the symptoms of blocking, running, itching or sneezing occur for more or less than four days at a time or for more or less than four weeks. Intermittent rhinitis is not the same as seasonal allergic rhinitis. Approximately 50 percent of sufferers are sensitive to housedust mite. Similarly, persistent allergic rhinitis can be due to seasonal pollens. The pathophysiology in children is the same as that in adults (see Chapter 109, Allergic rhinitis), however, since sensitization starts locally in the nose, skin prick tests may be negative for the first year or two of symptoms in children. Small children may be food allergic and have rhinitis as an additional symptom to atopic dermatitis, asthma or failure to thrive. Cow's milk and egg proteins are the commonest responsible allergens. With increasing age these food sensitivities are usually lost and inhalant sensitivities (housedust mite, animal dander) gained.²⁷ Pollen allergy usually begins later with peak incidence in the teenage years.

VIRAL RHINITIS

The usual presentation is with a sore throat progressing to sneezing, rhinorrhea, malaise and discomfort. Rhinoviruses cause over a third of viral colds and have many different subtypes without immune cross protection. Gwaltney²⁸ has shown that paranasal sinus membranes are involved in the common cold and may remain involved for up to six weeks after, although symptoms usually remit within days. Eighty percent of paediatric asthma exacerbations begin with a viral rhinitis.²⁹ Severity is increased if the allergic asthmatic child is also exposed to relevant allergens at the same time.³⁰ These

observations are probably extendable to the sinuses and middle ear with viral upper respiratory infections precipitating sinusitis and acute otitis media.

ACUTE SINUSITIS AND RHINOSINUSITIS

Acute sinusitis typically presents clinically in the maxillary sinuses though a pansinusitis with involvement of the ethmoidal frontal and sphenoidal sinuses is the norm. Infection is probably initially viral, sometimes with subsequent bacterial superinfection. The organisms most frequently implicated are *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Moraxella catarrhalis*. Clinically, there may be facial pain, purulent rhinorrhea and headache, particularly if the frontal sinus is involved. Classical treatment is with analgesia and antibiotics,³¹ possibly plus decongestants and/or steam inhalation. Antibiotics are not always necessary as the infection is often viral.^{28, 32} A recent review of the four Cochrane reviews of antibiotics in upper respiratory tract infections³³ states that antibiotics may be effective for acute radiologically confirmed maxillary sinusitis, with a number needed to treat (NNT) of three to six, and suggests that clinicians should weigh up the modest benefits with the potential for adverse effects. [****] Since radiology is not readily available, the American criteria³¹ of choosing to treat with antibiotics only those patients with moderately severe maxillary pain and/or tenderness in the face or teeth (especially unilateral) and purulent rhinorrhea lasting more than seven days following a cold, plus those with severe symptoms (especially those with unilateral facial pain) regardless of the duration of illness, seem sensible. The antibiotic chosen should be the most narrow spectrum agent available against the likely pathogens.

Recent studies suggest that additional use of topical nasal corticosteroids^{34, 35} or antihistamine³⁶ plus antibiotics is associated with a more rapid resolution of symptoms. [***] Intranasal mometasone alone was superior to oral amoxycillin in a recent trial in acute rhinosinusitis with symptoms persisting beyond seven days but without severe symptoms and signs.³⁷

Acute pyogenic infection which spreads beyond the confines of the paranasal sinuses may give rise to the orbital and intracranial complications described later under Complications of sinusitis in children.

CHRONIC RHINOSINUSITIS

Magnetic resonance imaging (MRI) studies in children with neurological disease reveal that 45 percent have radiological evidence of rhinosinusitis.³⁸ The distribution differs from that in adults, affecting posterior sinuses more commonly. There is evidence that paediatric rhinosinusitis remits with increasing age at around seven

years, in similar fashion to otitis media with effusion. The symptoms include cough, and chronic rhinosinusitis has been mistaken for asthma.³⁹ The pathophysiology may include allergic reactions to infective organisms such as bacteria and viruses.

There are some special forms of paediatric rhinosinusitis which are discussed in the following section.

Primary ciliary dyskinesia

Primary ciliary dyskinesia is an inherited (autosomal recessive) condition, involving abnormalities of either the structure of the inner or outer dynein arms, radial spokes or mitochondria of cilia or ciliary coordination.⁴⁰ Infective organisms include *Haemophilus influenzae*, *Staphylococcus aureus* and *Pseudomonas*. Recent evidence suggests that lack of inducible nitric oxide synthase (iNOS) in the epithelial membrane may be the underlying pathogenic factor since formation of nitric oxide is intimately linked with the ability of cilia to beat.⁴¹ Affected individuals suffer from rhinosinusitis symptoms from birth, usually accompanied by lower respiratory tract problems. Half of affected patients have associated dextrocardia (Kartagener's syndrome). Later, subfertility is common. Douching with saline has some symptomatic benefit.

Cystic fibrosis

This autosomal recessive inherited condition involves abnormalities of the chloride channel in secretory cells leading to thick sticky mucus which moves poorly. Several different mutations on the long arm of chromosome 7 have been identified, the most common affecting the delta 508 gene.⁴² Symptoms include rhinosinusitis (plus polyps in 7–32 percent of children), recurrent or chronic chest infections and (because pancreatic secretions are affected) digestive problems with malabsorption.^{43, 44, 45} The rhinosinusitis appears predominately infective with neutrophils and macrophages present in both nose and chest.⁴⁶ Raised cytokines are TH1 type: IL8 and interferon gamma.⁴⁷

There is thus usually a poor response to topical corticosteroids. However, recent investigations have demonstrated that in 50 percent of cystic fibrosis sufferers there is a nasal eosinophilia and that this subset of patients may show some response to topical corticosteroids.⁴⁸ The most common infecting organism is *Pseudomonas aeruginosa*, often present in 'biofilm' form and therefore resistant to antibiotic usage. Nebulized tobramycin has been shown to be helpful.⁴⁹ Until recently, heterozygotes for cystic fibrosis genes have been assumed to be asymptomatic. However, a recent study shows that they are over-represented in the childhood rhinosinusitis population.⁵⁰

Transient hypogammaglobulinaemia

Maturation of the immune system is slow in some children who experience recurrent infections once the level of maternal immunoglobulin subsides at around three to six months. Subsequent delayed maturation takes place so that by around three years the child is no longer seriously troubled.⁵¹ Prophylactic antibiotics, particularly in the winter months when viral infections may predispose to secondary bacterial ones, are helpful until spontaneous remission occurs.⁵²

IgA/IgG SUBCLASS DEFICIENCY

IgA, commonly called 'mucosal antiseptic paint' is passed into secretions on mucosal surfaces where it prevents bacteria and viruses from attaching to epithelial cells. Deficiency of IgA is common in the population, affecting around 1/5000 people, half of whom suffer from recurrent infections. The remainder probably successfully utilize IgM as a secretory antibody. Transient IgG deficiency can occur in childhood, with adult levels only being reached by around age 12.⁵³

IgG subclass deficiency compounds lack of IgA and may on its own increase upper respiratory tract infections.⁵⁴ There are four IgG subclasses (IgG 1–4). IgG1 is directed against protein allergens and makes up some 60–70 percent of the total; therefore, deficiencies in other subclasses may be missed if only total immunoglobulin levels are measured since the total IgG level is normal. IgG2 is manufactured against carbohydrates. Since many of the organisms affecting the upper respiratory tract in childhood are carbohydrate coated (*Haemophilus influenzae*, *Staphylococcus aureus*, *Streptococcus pneumoniae*), this deficiency is probably relevant in 5 percent of the paediatric rhinosinusitis population, some of whom fail to make adequate antibody responses to Pneumococcal or H-influenzae B immunization.^{55, 56}

MANNOSE BINDING LECTIN DEFICIENCY

Mannose binding lectin (MBL) is capable of attaching neutrophils to carbohydrates on organisms such as bacteria and fungi. It is a complex eight-chained polypeptide and genetic single amino acid mutations occur causing reduced levels in 5 percent of the population. These individuals are infection-prone, particularly before the age of two years, after which maturation of the IgG2 subclass can take over MBL function.⁵⁷ Deficiency of MBL exacerbates other humoral immune deficiencies.⁵⁸

Acquired immune suppression

Iatrogenic immune deficiency, particularly following use of corticosteroids and cytotoxic drugs, can result in infections including rhinosinusitis.⁵⁹

Diabetes mellitus, if poorly controlled, can be associated with acute sinusitis or with a chronic form, sometimes with fungi present. Chronic diseases such as **renal failure** are associated with an increased prevalence of upper respiratory tract infections.

Lack of splenic function, either due to previous surgical removal or compromise by diseases such as sickle cell anaemia and malaria, is associated with impaired resistance to infection, particularly with Pneumococci. Polyvalent pneumococcal vaccine should be given prior to splenectomy and patients followed for their ability to make anti-pneumococcal responses.

Protein-calorie malnutrition is common in poorer countries, but milder forms exist in affluent western societies where children frequently have poor diets due to excess consumption of junk foods. Iron deficiency anaemia was thought to be associated with susceptibility to infection, but a recent paper disputes this.⁶⁰

DIAGNOSIS

Diagnosis rests on a detailed history, supported by examination findings. A standard proforma may be helpful. Particularly relevant points are: past evidence of allergic disease (atopic dermatitis, asthma), purulence of nasal discharge, whether this ever remits, and the length of the history.

Associated conditions are common and enquiries should be made about otitis media with effusion, tonsillitis, sleep disorders, asthma and chest infections.

Environmental influences such as allergens present in the home, parental smoking and day care are relevant.^{61,62} In small children a feeding history, particularly of colic or other food reactions, or drinking a bottle whilst lying down, may point to reflux as a possible cause.

A differential diagnosis includes obstructive disorders such as choanal atresia and foreign body, particularly if the problem is unilateral. Adenoid hypertrophy with post-nasal space bacterial colonization also presents with similar symptoms to those of chronic rhinosinusitis.

EXAMINATION

External examination should include a check for an allergic nasal crease or Denny's lines (extra creases under the eyes) plus other evidence of allergy such as atopic dermatitis. Ability to nose-breathe should be tested together with some estimation of the nasal airway which can be as simple as spatula testing.

Internal examination of the nose can be carried out gently with an otoscope. Nasendoscopy will provide more detail, but is difficult in small children without anaesthetic.

The state of the mucus membranes, nature of any discharge and any structural abnormalities should be noted.

Examination of the throat, ears and lower respiratory tract should also be undertaken, together with some functional lower respiratory tract measurement such as peak flow, in all children with upper respiratory tract disease.²⁶

INVESTIGATIONS

Skin prick testing

This can be undertaken even in small children, in whom the back is a useful site whilst they are being cuddled by a parent or carer. As with adults it is wise to exclude patients with anaphylaxis, severe atopic dermatitis, recent antihistamines and dermagraphism. Blood RAST (see Chapter 109, Allergic rhinitis) tests can be substituted looking for allergens suggested by the history.

As with adults, a positive and negative control should be included. A wheal 2 mm greater than the negative control is regarded as positive. However, false positive results occur and observations must be interpreted in the light of the patient's history (**Figure 83.1**).

Blood tests

In refractory rhinitis and rhinosinusitis, some if not all of the following investigations may prove helpful:

- full blood count and differential, including eosinophil count;
- iron studies;
- immunoglobulins;
- IgG subclasses, MBL;
- total IgE and IgE to specific allergens which are either unavailable for skin prick testing or when skin prick testing is contraindicated.

Radiology

Sinus x-rays correlate poorly with computed tomography (CT) scans⁶³ and are very rarely necessary. One possible

© Hodder Arnold / Scott-Brown 7E

Figure 83.1 Skin prick testing.

exception is acute rhinosinusitis not resolving with therapy after 48 hours, when a plain x-ray may show an empyema of the maxillary antrum. A chest x-ray can be helpful if primary ciliary dyskinesia is suspected since it may show dextrocardia in Kartagener's syndrome.

CT scans of the paranasal sinuses are abnormal in over one-third of children for six weeks after a viral cold, demonstrating sinus inflammation. They are rarely helpful as a diagnostic procedure unless abnormalities such as choanal atresia or encephalocele are suspected in a child with predominately obstructive symptoms or if extension of acute sinusitis to the orbit or the brain is suspected. Otherwise they provide a useful road map in rare cases where surgical intervention is necessary.⁶⁴

Other specialist tests include:⁶⁵

- nasal mucosal ciliary clearance as assessed by saccharin clearance time;
- ciliary beat frequency as assessed by phase contrast electron microscopy;
- ciliary ultrastructure using the electron microscope;
- nitric oxide measured by chemiluminescence on expired air and intranasally;
- sweat tests and/or genetic analysis for cystic fibrosis;
- pH or impedance monitoring in suspected gastro-oesophageal reflux disease;
- audiometry and tympanometry where there is a suspicion of hearing impairment or speech and language disorder.

TREATMENT

Treatment of allergic rhinitis detailed in the ARIA guidelines²⁶ is based upon the frequency and severity of disease (see Figures 109.1 and 109.4 in Chapter 109, Allergic rhinitis).

Allergen avoidance

Since hayfever sufferers do not experience hayfever symptoms outside the grass pollen season, it seems that allergen avoidance is effective. However, evidence for the effectiveness of allergen avoidance measures in the treatment of rhinosinusitis is lacking.

Pharmacotherapy

The same preparations are used in paediatric as in adult rhinitis. Special paediatric considerations are as follows:

- **antihistamines:** sedating antihistamines impair academic performance and should be completely avoided;⁶⁶
- **sodium cromoglicate:** this is weakly effective and needs to be used several times a day, but is the only nasal spray licensed for children under four years in the UK;

- **topical corticosteroids:** the metanalysis demonstrates that these are the most effective form of treatment for allergic rhinitis^{67,68} [****] and this is also true in children under four years of age where fluticasone propionate was shown to be superior to ketotifen syrup.⁶⁹ They are licensed either for four, six or twelve years upwards and it is important that those which have a systemic bioavailability (betamethasone, dexamethasone, second generation topical corticosteroids) are used only briefly. For long-term use, fluticasone or mometasone appear to be least absorbed.⁷⁰ Care should be taken to monitor growth since this is a very sensitive measure of systemic effect, particularly in children receiving corticosteroids at more than one site;
- **leukotriene receptor antagonists (LTRAs):** although these drugs have efficacy in allergic rhinitis, they are no more effective than antihistamines and are similarly expensive. As with adults, some individuals obtain more benefit than others from this form of therapy. Even if combined with an antihistamine the efficacy is not greater than that of an inhaled corticosteroid.⁷¹ Consideration should be given to the use of LTRAs in order to try and reduce steroid dose in children with multiple problems (such as rhinitis, asthma and eczema) who are receiving corticosteroids at more than one site;⁷²
- **Decongestants:** oral decongestants are ineffective and have significant side effects such as hyperactivity and insomnia. [****] Topical decongestants can cause rebound with a blocked unresponsive nasal mucosa (rhinitis medicamentosa) if used for more than a few days at a time.⁷³ They are best used during the thick phase of a cold, on flying or at the start of therapy when the nose is considerably blocked.

There are very few trials of therapy for chronic rhinosinusitis, especially in children. Removal of possible underlying contributing factors (allergens, pollution, infection), would seem sensible. Nasal douching in adults reduces symptoms and improves quality of life. The literature on antibiotics and antifungal agents topical or oral remains confused,⁶⁴ but there is evidence of benefit from tobramycin topically in cystic fibrosis.⁷⁴

Immunotherapy

IMMUNE REPLACEMENT THERAPY

Some individuals with severe immunoglobulin defects respond to immunoglobulin replacement therapy.⁵⁶ However, this is not usually employed for rhinosinusitis in isolation. Very severe immune deficiency such as T-cell problems may necessitate bone marrow replacement therapy.

BACTERIAL VACCINES

Once widely used, mixed vaccines containing several bacterial antigens were abandoned in the UK after double-blind, placebo-controlled studies showed no efficacy. Some are some available in Europe, with small trials suggesting reduction of reinfection in children.⁷⁵

PNEUMOVAX® (ANTI-PNEUMOCOCCAL VACCINE)

This is effective presplenectomy.

Sublingual immunotherapy

Immunotherapy using preparations of the rhinitis-producing allergen to induce tolerance (desensitization) has been in vogue for many years, usually relying on subcutaneous injection. Sublingual immunotherapy (SLIT) has recently been proposed as an alternative to the subcutaneous route and has been shown in both rhinitis and asthmatic patients to have a good safety profile with no severe systemic reactions reported.^{76,77} A recent Cochrane meta-analysis⁷⁸ concluded 'SLIT is a safe treatment which significantly reduces symptoms and medication requirements in allergic rhinitis. The size of the benefit compared to that of other available therapies, particularly injection immunotherapy, is not clear, having been assessed directly in very few studies. Further research is required concentrating on optimising allergen dosage and patient selection'.

Recent studies performed in large samples of patients have shown a clear dose-effect of tablet-based SLIT in patients with grass-pollen induced rhinoconjunctivitis.^{79,80,81} In one study in which subcutaneous and sublingual immunotherapy for seasonal rhinitis were compared, both were effective compared to placebo, although the study was underpowered to detect differences between the treatments.⁸² A further recent trial of grass allergen tablets for sublingual use demonstrated a 30–40 percent improvement in symptom and medication scores and an approximate 50 percent increase in the responder rate, compared to placebo.⁸³ A further follow-up for five years is planned in order to assess possible beneficial long-term effects.

SURGERY FOR PAEDIATRIC RHINOSINUSITIS

Adenoidectomy

There is growing evidence in the literature for adenoidectomy as a first line surgical intervention for chronic rhinosinusitis in children who have failed maximal medical treatment.⁸⁴ Hypertrophic adenoids block the posterior choanae, interfering with nasal airflow and the drainage of secretions. They harbour pathogenic bacteria

which proliferate rapidly after viral infection. In a recent prospective study, children with large obstructive adenoids showed a significant reduction in the number of episodes of infective rhinosinusitis per year following adenoidectomy.⁸⁵ However, a recent metaanalysis of (adeno-) tonsillectomy involving six randomized and seven nonrandomized trials with 1596 person years data on upper respiratory tract infections demonstrated a pooled risk difference of only -0.5 episodes per year postoperatively (95 percent CI -0.7 to -0.3).⁸⁶ [****] The advent of suction diathermy adenoidectomy has greatly reduced the risks of primary and secondary haemorrhage and, due to the greatly reduced perioperative blood loss, has made adenoidectomy safe in young children.⁸⁷ [***]

Maxillary antral washout

Maxillary antral washout used to be the most commonly performed sinus procedure performed in children. The rationale behind it is that it irrigates infective material out of the sinus through the natural ostium, thereby restoring its patency. Infected secretions were washed out and mucosal blood flow improved. However, since the advent of CT scanning it has been found that over 70 percent of children have involvement of their ethmoid sinuses in chronic rhinosinusitis and that one irrigation of the maxillary antrum rarely clears the symptoms.⁸⁸

Inferior meatal antrostomy

Creation of an inferior meatal antrostomy does not improve the movement of secretions towards the natural ostium. Despite the creation of an inferior meatal antrostomy, continued obstruction of the osteomeatal complex results in retained secretions and persistent disease. A high failure rate has been reported for this procedure in children with chronic rhinosinusitis and most surgeons have abandoned this procedure, except in children with cystic fibrosis and primary ciliary dyskinesia where gravity is needed to drain sinus secretions as normal mucociliary function is absent. [***]

Turbinate reduction surgery

Surgery to reduce the bulk of the inferior turbinates is sometimes advocated to improve symptomatic nasal obstruction. A multitude of techniques – linear cautery, diathermy, cryosurgery, laser reduction partial excision and submucous resection – have been described. Benefits are short lived and there is significant morbidity with risk of bleeding, postoperative pain and discomfort, troublesome crusting of the nasal secretions and intranasal adhesions. The evidence base for these

techniques is weak but best results seem to be with formal submucous resection and a turbinate lateralization procedure.⁸⁹ [***/**] Many otolaryngologists empirically offer turbinate reduction surgery where the predominant symptom is nasal obstruction. Turbinectomy is considered in Chapter 125, The management of enlarged turbinates.

Endoscopic sinus surgery

In 1996 a group of otolaryngologists with a specific interest in paediatric rhinosinusitis met in Brussels and created a consensus document in which they described absolute and possible indications for paediatric endoscopic sinus surgery (ESS).⁹⁰ These are shown in Table 83.1.

A coronal CT scan of the paranasal sinuses with coronal 4 mm cuts using bony windows should be obtained in all patients in whom endoscopic sinus surgery is being considered. This will both define the extent of the disease and provide a road map of the anatomy so that damage to vital structures may be avoided.

The most commonly used technique is an anterior to posterior dissection, as described by Messerklinger in 1978,⁹¹ which is well suited to limited disease affecting the anterior ethmoids, maxillary sinus and frontal sinus. Fashioning of a middle meatal antrostomy can be difficult in the child due to the narrow infundibulum. Paediatric endoscopes (2.7 mm) and instruments are now available, which together with the microdebrider have greatly improved surgical precision. In an attempt to reduce adhesions, some surgeons leave stents in the middle meatus. These are usually removed under general anaesthetic at seven to ten days.⁹²

Metanalysis of all the current evidence suggests that paediatric ESS for chronic sinusitis achieves treatment goals in 88 percent.⁹³ Unfortunately, the results in children with cystic fibrosis are not so encouraging with a recurrence rate of 50 percent within 12 months.⁹⁴

In the early 1990s, two studies involving piglets demonstrated significant changes in facial growth following sinus surgery.^{95,96} Subsequently, two papers involving

humans suggest that the risk is less substantial and no discernable change in facial anthropometric measurements were seen ten years after ESS.^{97,98}

The role of endoscopic sinus surgery in paediatric sinusitis is still evolving but the technique appears safe without long-term side effects; however adenoidectomy should be the first step in young children with adenoidal hypertrophy and nasal symptoms unresponsive to medical treatment. [****]

COMPLICATIONS OF SINUSITIS IN CHILDREN

Complications of paranasal sinus disease are more common in children than adults. The spread of infection from the nose and paranasal cavities to the surrounding brain and orbit is facilitated in children by dehiscences in the common bony walls at the suture lines, the thinness of the cranial bones and the relative immunosuppression of the child under the age of five.

The incidence of serious complications of sinusitis has steadily declined since the advent of antibiotics, but orbital and intracranial complications still occur (Table 83.2). Intracranial spread occurs through septic venous phlebitis in the venous system which drains the brain and paranasal sinuses. This whole venous system is devoid of valves and there are no lymphatic vessels or lymph nodes in the orbit to trap infection. [****/**]

Local complications

ORO ANTRAL FISTULA

An oro antral fistula is an abnormal communication between the floor of the maxillary sinus and the roof of the oral cavity. It is usually caused by extraction of a molar tooth in the older child. If identified early, simple gingival closure can be successful. Once the fistula is established it discharges foul smelling green pus which requires systemic antibiotics and maxillary antral lavage. Large oro antral fistulae require surgical repair using local mucosal flaps with or without buccal fat grafts.⁹⁹

Table 83.1 Indications for paediatric endoscopic sinus surgery.

Indications	Relative indications
Complications of sinusitis	Persistent signs and symptoms with CT findings consistent with clinical disease
Symptomatic mucocoeles	Symptomatic concha bullosa
Systemic disease complicating sinusitis	Chronic headache with abnormal CT
Recurrent or chronic sinusitis persisting for six months despite medical therapy	Chronic nasal discharge
	Recurrent sinusitis with normal CT

Table 83.2 Complications of paediatric rhinosinusitis.

Local complications	Orbital complications	Intracranial complications
Oro antral fistula	Periorbital cellulitis	Meningitis
Mucocoele	Subperiosteal abscess	Intracranial abscess
Osteomyelitis	Orbital abscess	
	Cavernous sinus thrombosis	

MUCOCOELES

Mucocoeles are epithelial-lined mucous containing cysts which can completely fill a paranasal sinus. They can be classified as primary or secondary. Primary mucocoeles are mucous retention cysts which are common and usually asymptomatic, situated in the floor of the maxillary sinus. Secondary mucocoeles are due to obstruction of a sinus ostium due to inflammation, which causes the retention of secretions under pressure. Secondary mucocoeles are very rare in children but when they do occur the most common site is the frontoethmoids. In children with cystic fibrosis, however, the maxillary sinus is most commonly affected. The wall of the cyst releases osteolytic substances and can cause expansion of bone, presenting as a space-occupying lesion and acting as a benign tumour.¹⁰⁰

Frontoethmoid mucocoeles cause displacement of the orbit leading to progressive diplopia, proptosis and limitation of ocular movement. It is not uncommon for children to initially present to an ophthalmologist because of this. Bulging of the medial nasal wall causes nasal obstruction. Vertex headache is frequent and may be the only symptom in the cases of isolated sphenoid mucocoeles although pressure on the optic nerve will cause visual disturbance.¹⁰¹

Plain x-rays of the paranasal sinuses are of little use in evaluating mucocoeles. The investigation of choice is CT scanning. Mucocoeles are seen as round or oval homogenous masses involving one or more paranasal sinuses and causing compression of the surrounding structures due to expansion of the bony walls of the affected sinus.

Mucocoeles require surgical intervention. Frontoethmoid mucocoeles have traditionally been marsupialized using an external frontoethmoidectomy approach and extensive surgery using osteoplastic flaps and cranialization of the frontal sinus has also been described. Within the last decade, however, there is increasing evidence of the suitability of endoscopic sinus surgery in the treatment of paediatric mucocoeles and thus avoiding external scars.^{102, 103}

OSTEOMYELITIS

Osteomyelitis of the frontal bone is a rare complication of frontal sinusitis. Less than 20 cases have been reported in

the literature within the last decade. Teenagers are most commonly affected and initial presentation is with local headache and tenderness. Infection in the frontal sinus can cause an osteomyelitis of the frontal bone. Suppurative material may then breach the cortex of the frontal bone causing subperiosteal abscess formation in the tissues of the forehead. This creates a boggy swelling which was first described by Sir Percival Pott in 1760 and consequently is named ‘Pott’s puffy tumour’.

Frontal bone osteomyelitis can also cause subdural, epidural and periorbital abscesses as well as secondary septic thrombosis of the dural sinuses and is associated with severe neurological sequelae in 20 percent of patients.¹⁰⁴

The causative organisms are Gram-positive cocci including *Streptococcus*, *Staphylococcus* and oral anaerobes. Initial treatment consists of the administration of intravenous antibiotics such as penicillin, flucloxacillin and metronidazole.

CT scanning of the brain and paranasal sinuses is the most appropriate investigation as it will show which sinuses are involved and can detect intracranial or soft tissue spread of infection. Chronic or early osteomyelitis can be detected using a technetium 99 bone scan.

Surgical intervention is needed if the CT scan shows a complication of frontal sinusitis such as abscess formation. Frontal sinus trephine through an external eyebrow incision and maxillary antral washout under anaesthetic are usually sufficient to clear the pus in the sinuses. The osteoplastic flap procedure removing sequestered frontal bone with secondary acrylic plate reconstruction is very rarely needed. [**]

Orbital complications

Infection may spread through the thin party wall (lamina papyracea) separating the ethmoidal sinuses from the orbit. If confined to the anterior part of the orbit in front of the fibrous septum, which protects the more posterior contents of the globe, ‘periorbital’ or ‘pre-septal’ cellulitis ensues. Spread behind the septum and into the globe proper is the far more dangerous ‘orbital cellulitis’ (Figure 83.2). Periorbital cellulitis is the most frequently occurring complication in children. Children with orbital complications of sinusitis commonly present to ophthalmologists and paediatricians, as well as otolaryngologists, and their successful management depends on cooperation between these specialities.¹⁰⁵ The reason for this is the importance of the assessment of the child’s eye and general clinical condition. The difficulty for the clinician lies in distinguishing periorbital cellulitis, which will usually resolve with antibiotics, from subperiosteal or orbital abscess which requires surgical drainage.

In one series, 70 percent of children presenting with periorbital cellulitis were under nine years old and 70 percent of these had medically treatable periorbital

© Hodder Arnold / Scott-Brown 7E

Figure 83.2 Orbital cellulitis.

cellulitis. Despite modern surgical techniques and appropriate antibiotics, blindness is still a real risk in children as a result of orbital infection. The older the child at presentation the greater the risk of subperiosteal abscess, orbital abscess or cavernous sinus thrombosis.¹⁰⁶

In 1970, James Chandler published an excellent paper in which he describes both the pathogenesis and management of the orbital complications of sinusitis and his classification system, as shown in Table 83.3, is still used today.¹⁰⁷

PERIORBITAL CELLULITIS/SUBPERIOSTEAL ABSCESS/
ORBITAL ABSCESS

Unfortunately, when a child presents with periorbital cellulitis it is not easy to define which stage the disease has reached on clinical signs alone and it must be remembered that half of cases with intracranial complications present with periorbital cellulitis.¹⁰⁸ On the other hand, the great majority (75–80 percent) of periorbital cellulitis in children resolves with antibiotic treatment alone.¹⁰⁹ For these reasons protocols are needed to ensure that each patient is appropriately treated and to reduce the incidence of complications.¹¹⁰ In the UK, all children with periorbital cellulitis are admitted for the administration of

intravenous antibiotics. Traditionally, penicillin, flucloxacillin and metronidazole have been used as the commonest pathogens isolated were *Streptococcus*, *Staphylococcus* and *Haemophilus influenza* type b. Since the advent of the Hib vaccine, haemophilus infections are much rarer and only occur in unimmunized children.¹¹¹ Anaerobes such as bacteroides are part of the natural nasal flora and rarely cultured except in chronic rhinosinusitis and some brain abscesses. However, it is prudent to include anaerobic cover from the outset. In areas where beta lactamase-producing bacteria are common, the antibiotic combination should be changed to either cefuroxime and metronidazole or co-amoxycyclavulanic acid. Intranasal decongestants and irrigation with saline are routinely used but their benefit has not been scientifically evaluated. Regular and adequate analgesia is required.

The patient should be closely monitored by documenting neurological state, the temperature and white-cell count. Colour vision, visual acuity, eye movements and papillary reflexes should be checked once or twice per day by an ophthalmologist.¹¹¹ Worrying features include worsening proptosis, visual disturbance, reduced or painful eye movement and high fever. If there is no improvement in clinical signs after 24 hours of appropriate intravenous antibiotics, a CT scan of the paranasal sinuses and brain with contrast should be ordered urgently. Other indications for CT scanning are as follows:¹¹⁰

in orbital complications

- central neurological signs;
- inability to perform adequate ophthalmological examination;
- no improvement in orbital signs or general clinical condition after 24 hours of appropriate intravenous antibiotics;
- deterioration of orbital signs (proptosis, ophthalmoplegia, altered colour vision, or visual acuity).

Surgical intervention is required if there is evidence of a collection of pus, either subperiosteally, within the orbit or intracranially. The aim of surgery is to drain the pus, release the pressure on the orbit and to provide material for microbiological culture. Extensive sinus surgery is unjustified as orbital complications are usually the result of acute sinus infections. The location of the abscess will dictate if an endoscopic approach is feasible.¹¹² Endoscopic drainage avoids external scars and results in rapid resolution of periorbital inflammation. The anatomical limits of the paediatric nose and the vascular mucosa make it technically difficult but excellent results have been reported in expert hands.¹¹³ An external ethmoidectomy with bilateral maxillary antral washout has stood the test of time. If a subperiosteal abscess is encountered, it can be drained into the nose through a subtotal ethmoidectomy. In the presence of pus trapped in the frontal sinus, a trephination of the frontal sinus floor can be performed at the same time. If an orbital abscess is present, it can be

Table 83.3 Chandler's classification of orbital infection.

Stage	
1	Inflammatory oedema
2	Orbital cellulitis
3	Subperiosteal abscess
4	Orbital abscess
5	Cavernous sinus thrombosis

drained via a linear incision around the orbit through the tarsal plate of the upper eyelid. Intravenous antibiotics should be continued for a further 48 hours and then oral antibiotics for a further 10–14 days.¹¹⁴

CAVERNOUS SINUS THROMBOSIS

Cavernous sinus thrombosis results from septic phlebitis of the ophthalmic veins and involvement of the cavernous sinus. Initially, the orbital signs are unilateral but these become progressively bilateral causing proptosis with third, fourth and sixth cranial nerve palsies. Signs of meningitis are frequently present and there is dilation of the episcleral veins, which is a distinctive feature. It can prove to be fatal with quoted mortality rates of 30 percent.¹¹⁵ CT scanning of the head with contrast will confirm the diagnosis. Intravenous broad-spectrum antibiotics should be started immediately, together with heparin anticoagulation. *Staphylococcus aureus*, *Streptococcus* and *Pneumococcus* are the most likely organisms. High-dose systemic steroids will reduce oedema around the orbital apex and should be given. Orbital exploration and drainage of involved paranasal sinuses is urgently needed so as to drain an orbital abscess and decompress the orbit. Intravenous antibiotics will be needed for several weeks for an optimal outcome.¹¹⁶ [**]

Intracranial complications

MENINGITIS

Meningitis is regarded as the most common intracranial sinogenic complication.¹¹⁷ The clinical presentation is headache, neck stiffness and a high fever in the presence of purulent rhinorrhea. Febrile convulsions and vomiting may occur. However, it must be remembered that, in one-third of children, neck stiffness will not be demonstrable.¹¹⁴ In young children it can be difficult to distinguish meningitis from intracranial abscess or encephalitis. CT scan of the brain with contrast should be undertaken before lumbar puncture to exclude intracranial lesions that could cause raised intracranial pressure.¹¹⁸

First-line treatment is with intravenous antibiotics. *Streptococcus pneumoniae*, *Haemophilus influenza* type b (Hib) and *Neisseria meningitidis* are the most common pathogens, although vaccination has virtually eradicated Hib meningitis in some countries. Drainage of the involved sinus is needed if either there is no improvement in clinical condition or intracranial involvement on CT scanning. Unfortunately, neurological sequelae such as sensorineural deafness and global delay are common after meningitis. The use of adjuvant corticosteroids is controversial but is beneficial in reducing the incidence of neurological sequelae in children.¹¹⁹ [**/*]

INTRACRANIAL ABSCESS

All intracranial complications of sinusitis are more common in male adolescents.¹²⁰ The management of intracranial abscess requires close cooperation between the otolaryngologist, neurosurgeon and paediatrician as it is life-threatening and requires immediate treatment. Intravenous broad-spectrum antibiotics with good cerebrospinal (CSF) penetration are needed, together with drainage of the involved sinus and its intracranial focus of infection.

Intracranial abscesses can be classified as extradural, subdural and intracerebral, depending on their anatomical location. Intracranial extradural abscess is due to infection in the space between the dura and bone and is almost exclusively a complication of frontal sinusitis with secondary osteomyelitis. It presents with local tenderness, fever and headache, but focal neurological signs and changes in conscious level are rarely seen. Both the affected sinus and the extradural abscess require surgical drainage, either endoscopically or externally.

Subdural infection (Figure 83.3) is very rare but is a serious complication of frontal sinusitis. It carries a 25–35 percent mortality rate and, of those who survive, 30 percent will have permanent neurological impairment.¹¹⁷ It tracks over the frontal lobes in the subdural space and can spread into the interhemispheric region leading to a parafalcine abscess. The presenting features are of worsening headache, vomiting, seizures and rapid loss

Figure 83.3 •Subdural empyema due to frontal sinusitis (arrowed).

of consciousness with specific neurological signs depending on the site of the abscess. CT or MRI are used to make the diagnosis. Treatment consists of intravenous broad-spectrum antibiotics and a combined neurosurgical and otolaryngological procedure to achieve drainage of the affected sinus and subdural abscess. Perioperative steroids and anticonvulsants are used to reduce the effects of raised intracranial pressure.

Ten percent of intracerebral abscesses in children are secondary to sinusitis or mastoiditis. This is significantly less frequent when compared to data collected prior to the 1980s.¹²¹ Unfortunately, the mortality rate of those affected remains unchanged at about 25 percent. The frontal and parietal lobes are most commonly affected. The symptoms are those of raised intracranial pressure, fever, seizures and loss of consciousness. Diagnosis is by imaging with CT or MRI. Lumbar puncture is contraindicated as there is a distinct likelihood that it will cause coning of the brainstem. As a result of scarring of cerebral tissue, postoperative epilepsy occurs in approximately one-third of children who undergo excision of their intracerebral abscess and therefore CT guided aspiration and intravenous antibiotic treatment is advocated to reduce this risk.¹²² [**]

KEY POINTS

- Paediatric rhinitis/rhinosinusitis is very common.
- Paediatric rhinosinusitis is usually treatable with medication and surgery is rarely needed.
- Imaging is rarely needed to make the diagnosis.
- In allergic rhinitis, skin prick tests may be negative for the first year or two of symptoms in children.
- IgA/IgG subclass deficiency is common in the population and should be considered as a cause of recurrent rhinosinusitis.
- Complications of infective sinusitis are rare but potentially fatal. Early recognition and treatment help to reduce morbidity.

Best clinical practice

- ✓ Indications for prescribing antibiotics in rhinosinusitis are: moderately severe maxillary pain with tenderness in the face and purulent rhinorrhea lasting more than seven days following a cold. [Grade B]
- ✓ The antibiotic chosen should be the most narrow spectrum agent available against the likely pathogens. [Grade B]

- ✓ Additional use of topical nasal corticosteroids or antihistamine plus antibiotics is associated with a more rapid resolution of symptoms in acute sinusitis. [Grade B]
- ✓ Intranasal steroids are the most effective form of treatment for allergic rhinitis. [Grade A]
- ✓ Oral decongestants are ineffective in rhinitis. [Grade A]
- ✓ There is growing evidence in the literature for adenoidectomy as a first line surgical intervention for chronic rhinosinusitis in children who have failed maximal medical treatment. [Grade C]
- ✓ In orbital cellulitis, if there is no improvement in clinical signs after 24 hours of appropriate intravenous antibiotics, a CT scan of the paranasal sinuses and brain with contrast should be ordered urgently. Surgical drainage of a subperiosteal or orbital abscess may be required. [Grade C]
- ✓ Lumbar puncture is contraindicated in sinogenic meningitis as there is a risk that it will cause coning of the brainstem. [Grade C/D]

Deficiencies in current knowledge and areas for future research

- There is much ongoing work on the epidemiology of upper respiratory tract allergy in children. The respective roles of hereditary factors, viral infections in early infancy and early exposure to antigens are still unclear.
- Knowledge of the pathophysiology of allergic rhinitis – including the role of nitric oxide – continues to be refined.
- The evidence base for surgical interventions in paediatric rhinosinusitis needs to be improved.

Adenoidectomy	1097		

SEARCH STRATEGY

The data in this chapter are supported by searches from the Guidelines database at the National Electronic Library for Health, The Cochrane Library, Medline and PubMed using the key words adenoid, adenoidectomy and children.

INTRODUCTION

Santorini described the nasopharyngeal lymphoid aggregate or 'Lushka's tonsil' in 1724. Wilhelm Meyer coined the term 'adenoid' to apply to what he described as 'nasopharyngeal vegetations' in 1870. The adenoid forms part of Waldeyer's ring of lymphoid tissue at the portal of the upper respiratory tract. In early childhood this is the first site of immunological contact for inhaled antigens.

Historically, the adenoid has been associated with upper airway obstruction, as a focus of sepsis, and more recently with the persistence of otitis media with effusion.

DEVELOPMENT OF THE ADENOID

Lymphoid tissue can be identified at four to six weeks gestation, lying within the mucous membrane of the roof and posterior wall of the nasopharynx. Lymphoid tissue of the adenoid may extend to the fossa of Rosenmüller and to the Eustachian tube orifice as Gerlach's tonsil. The membrane is covered with stratified squamous epithelium. The adenoid receives a rich arterial supply from branches of the facial and maxillary arteries and the

thyrocervical trunk. Venous drainage is to the internal jugular and facial veins. Lymphatic drainage is to the retropharyngeal lymph nodes and upper deep cervical nodes, particularly the posterior triangle of the neck. Nerve supply is from sensory branches of the glossopharyngeal and vagus nerves.¹

The adenoid can be identified by magnetic resonance imaging (MRI) from the age of four months in 18 percent of children.² By five months of age, the adenoid could be identified in all of 290 children studied. Growth continues rapidly during infancy and plateaus between 2 and 14 years of age. Regression of the adenoid occurs rapidly after 15 years of age in most children. The adenoid appears to be at its largest in the seven-year-old age group.³ However, clinical symptoms are more common in a younger age group, due to the relative small volume of the nasopharynx and the increased frequency of upper respiratory tract infections. [****/***/**]

IMMUNE FUNCTION OF THE ADENOID

The function of the lymphoid tissue of Waldeyer's ring is to produce antibodies. The adenoid produces B cells,

which give rise to IgG and IgA plasma cells. Exposure to antigens via the nasal route is an important part of natural acquired immunity in early childhood. The adenoid appears to have an important role in the development of an 'immunological memory' in younger children.⁴ The removal of this tissue at a young age may be immunologically undesirable.⁵

In children aged four to ten years, adenotonsillectomy does not appear to cause significant immune deficiency, although a slight decrease in IgG, IgA and IgM levels was found in the postoperative period four to six weeks after surgery.⁶ The authors concluded that this represents a compensatory response of the developing immune system following a reduction of chronic antigen stimulation. Specific reduction in IgG may represent a reduction in antigenic stimulation. There appears to be no decrease in IgE after adenoidectomy.^{7,8}

The evidence that immune status is compromised by removal of the adenoid alone is inconclusive, as studies generally include children also having tonsillectomy.⁹ [**/**]

PATHOLOGICAL EFFECTS OF THE ADENOID

The adenoid may be implicated in upper respiratory tract disease due to partial or complete obstruction of the nasal choanae or as a result of sepsis.

Pathological manifestations include rhinitis, rhinosinusitis, otitis media and otitis media with effusion. Adenoiditis, acute or chronic, is considered by some to be a related but distinct infective entity.¹⁰

Otitis media with effusion

The benefit of adenoidectomy in the management of otitis media with effusion (OME) has traditionally been ascribed to the relief of anatomical obstruction of the Eustachian tube.¹¹ While this may be a contributory factor, it is clear that adenoid size and physical obstruction alone cannot account for the benefit following adenoidectomy where the adenoid is small.¹² Adenoid size in children with and without OME is not significantly different. It is likely that recurrent acute or chronic inflammation of the adenoid and increased bacterial load, particularly of *Haemophilus influenzae*,^{13,14} results in squamous cell metaplasia, reticular epithelium extension, fibrosis of the interfollicular interconnective tissue and reduced mucociliary clearance in children with OME compared to those without OME.¹⁵ These changes increase bacterial adherence. This is likely to contribute to the development of a 'biofilm' infection resulting in middle ear effusion (a biofilm infection may be defined as 'a structured community of bacterial cells enclosed in a self-produced polymeric matrix and adherent to an inert or living surface').¹⁶ There is now good evidence,

particularly from the TARGET study, to support consideration of 'adjuvant' adenoidectomy in children over the age of three who are undergoing insertion of tympanostomy tubes (see Chapter 72, Otitis media with effusion).

Chronic gastro-oesophageal reflux has also been implicated in the development of OME, as a result of inflammation of the nasopharynx and the adenoid.¹⁷ [**/**]

Recurrent acute otitis media

Randomized controlled trials of the management of recurrent acute otitis media have shown that adenoidectomy was not effective in reducing episodes of infection in children younger than two years during the follow-up periods of 7–24 months after surgery.^{18,19} It is likely that a partial maturational selective IgA deficiency is a causative factor in these 'otitis-prone' children.²⁰ Low-dose prophylactic antibiotic treatment is preferred to adenoidectomy in this group as a means of preventing recurrent otitis media and the sequelae of infection until maturation of the immune system occurs naturally.²¹ [****/**/**]

Upper airway obstruction and obstructive sleep apnoea

Obstructive sleep apnoea in childhood is considered in detail in Chapter 85, Obstructive sleep apnoea in childhood. The prevalence of severe sleep disturbance in children due to upper airway obstruction is estimated to be approximately 1 percent, with a peak incidence between three and six years of age, and an equal sex incidence.^{22,23}

Airway obstruction due to adenoidal hypertrophy may produce depressed arterial PaO₂ and elevated PaCO₂ levels, which return to normal after adenoidectomy.²⁴ The respiratory improvement following adenotonsillectomy also results in a significant increase in serum insulin-like growth factor-I (IGF-I),²⁵ accounting in part for the clinically observed growth spurt following surgery. Despite the widespread acceptance of the benefits of adenotonsillar surgery in these children, a Cochrane review of adenotonsillectomy for obstructive sleep apnoea found no randomized trials addressing the efficacy of surgery in managing obstructive sleep apnoea syndrome (OSAS) in children.²⁶

In a prospective study of 40 children undergoing adenoidectomy, with or without tonsillectomy, for upper airway obstruction, the radiographic estimate of the adenoid size correlated highly with the improvement in polysomnographic scores following surgery. No correlation between tonsil size and grade of obstructive sleep apnoea was found.²⁷ [**/**]

Rhinosinusitis

The reader is referred to Chapter 83, Paediatric rhinosinusitis. In a retrospective study of 48 children with chronic sinusitis undergoing adenoidectomy or adenotonsillectomy, improvement was reported in the majority following surgery, and only three children subsequently required functional endoscopic sinus surgery.²⁸

A prospective study of children with recurrent rhinosinusitis showed that adenoidectomy was effective in abolishing infective episodes of infection, and that few children went on to require functional endoscopic sinus surgery.²⁹ [**]

Olfaction

Olfactory sensitivity is reduced in relation to adenoid size, and this improves after adenoidectomy.³⁰ This may, in part, account for the poor appetite reported in children with adenoidal hypertrophy. [**]

Neoplasia

Unsuspected neoplasia of the adenoid (and tonsils) in childhood is rare. Non-Hodgkin's lymphoma is reported in a series of six children.³¹ Atypical lymphadenopathy, and persistent and asymmetric enlargement of the tonsils and adenoid, in the absence of infection are suspicious and should prompt early imaging and biopsy. Presentation is often assumed to be due to the more common infective and obstructive manifestations of adenotonsillar disease so the diagnosis is often delayed. [**]

ASSESSMENT AND MANAGEMENT

Clinical history

The history should form part of a full paediatric ENT history with special attention to symptoms of middle ear disease and nasal obstruction. Specific questions regarding sleep disturbance, eating and atopic symptoms are important. A family history of atopy may be relevant. A full history of medication, prescribed, over the counter and alternative or complementary, is important. In children in whom adenoidectomy is being considered, it is essential to positively exclude a history or family tendency of unusual bleeding or bruising, as a routine clotting screen may not confirm mild von Willebrand's disease.

Clinical examination

Assessment of the external nose should be made before rhinoscopy. In particular, look for a skin crease in the

supra-tip region that may indicate frequent nose rubbing from symptoms of rhinitis.

Simple anterior rhinoscopy in children may be carried out using a halogen light otoscope with a large speculum. This is generally tolerated better in children than examination with a Thudicum's speculum.

Assessment of the nasal airway may be made with a cold Lack's tongue depressor or large laryngeal mirror. Posterior mirror rhinoscopy is not usually possible in children, but many will tolerate nasendoscopy with topical intranasal local anaesthetic spray, such as co-phenylcaine. Topical cocaine should not be used in children.

Nasendoscopy is increasingly used to assess adenoidal status in an outpatient setting. It may be well tolerated by children and is recommended prior to a decision to undertake surgery where adenoidectomy is the only procedure being considered (Figure 84.1).³²

A grading system has been proposed to assist in the decision to recommend surgery.³³ In another study of 817 children, endoscopic assessment of adenoid size was highly correlated ($p < 0.001$) with nasal obstruction, snoring and the results of tympanometry, but not with purulent rhinorrhoea.³²

In children undergoing another surgical procedure, peroperative assessment of the adenoid with a rigid endoscope or mirror is recommended to confirm the need for adenoidectomy.³⁴ [**]

The correlation of adenoid size with lateral soft tissue radiograph of the nasopharynx is poor, but plain radiography may be helpful if adenoidectomy is the only surgical procedure indicated and the child is unable to tolerate nasendoscopy in the clinic.³⁵ A classification of adenoid size has been described by Clemens *et al.* (Table 84.1).³⁶

Figure 84.1 Endoscopic view of the adenoids.

Table 84.1 Clinical grading of adenoid size.

Grade	Description
Grade I	Adenoid tissue filling one-third of the vertical portion of the choanae
Grade II	Adenoid tissue filling from one-third to two-thirds of the choanae
Grade III	From two-thirds to nearly complete obstruction of the choanae
Grade IV	Complete choanal obstruction

Reprinted from Ref. 36, with permission from Elsevier.

While acoustic rhinomanometry is a useful research tool, and MRI provides extremely accurate volumetric estimation of the adenoid, these investigations are not applicable in clinical practice.^{3, 37}

Nasendoscopy of the nasopharynx to assess adenoid size at the time of surgery is probably the gold standard, while mirror examination underestimates choanal occlusion, and palpation is a poor measure of adenoid hypertrophy.³⁸ [***/**/*]

Preoperative investigations

Routine preoperative investigations are not indicated prior to adenoidectomy for children who are ASA grade 1 (a normal healthy patient, without any clinically important co-morbidity and without a clinically significant past/present medical history).³⁹

Guidance for children who are ASA grade 2 (a patient with mild systemic disease) is not given in the National Institute for Health and Clinical Excellence (NICE) guideline on preoperative tests. Specific investigations for sickle-cell disease, thalassaemia, Down syndrome and congenital heart disease are indicated as appropriate. Management of type 2 diabetes mellitus should follow local paediatric guidelines for diabetic children undergoing elective surgery.

ADENOIDECTOMY

Adenoidectomy with or without tonsillectomy and/or insertion of ventilation tubes is one of the most frequently performed surgical procedures in children. Traditional adenoidectomy is carried out under general anaesthesia with the child in the tonsillectomy position using the blind technique of curettage. Assessment of the adenoid is made digitally prior to curetting the adenoid from the nasopharynx, and haemostasis achieved with gauze swab tamponade. Techniques employing direct vision have the advantage of reduced blood loss (<4 mL versus >50 mL),³⁶ and the ability to remove adenoid tissue from the choanae, while avoiding trauma to the Eustachian

cushions.⁴⁰ Of these techniques, those with the largest clinical experience are the suction coagulator and the microdebrider. In a randomized controlled trial, the microdebrider was 20 percent faster than the curettage technique,⁴¹ but the suction coagulator is significantly cheaper than the microdebrider.⁴² Single use instruments such as these abolish any potential risk of infection transmission.⁴³ The Coblator[®] plasma field device may prove suitable for adenoidectomy, but as yet no published data are available. The KTP laser is associated with a high incidence of postoperative nasopharyngeal stenosis and is not recommended for adenoidectomy.⁴⁴

Where social and geographical factors allow,⁴⁵ and with appropriate surgical and anaesthetic techniques, pre-emptive fluid replacement, antiemetics and analgesia, the majority of children may be safely discharged home within six hours of adenoidectomy.^{46, 47, 48} [***/**/*]

COMPLICATIONS OF ADENOIDECTOMY

The complications of adenoidectomy include:

- bleeding;
- dental trauma;
- airway obstruction, due to:
 - retained swab;
 - nasopharyngeal blood clot;
- infection;
- cervical spine injury (particularly in Down syndrome);
- velopharyngeal dysfunction;
- regrowth of the adenoid.

Death

No data assessing the risk of death following adenoidectomy independent of tonsillectomy or general anaesthesia were found.

Bleeding

The reactionary haemorrhage rate, that is, bleeding following adenoidectomy, within 6–20 hours of operation is less than 0.7 percent, and if severe enough to require a return to theatre, postnasal packing is the preferred management in the UK for haemostasis.⁴⁹ This study suggests that postnasal packing left *in situ* for four hours post-haemorrhage is as effective as packs left for 24 hours. A small number of consultants in this questionnaire study (3/285) electively admitted children to an intensive care facility following postnasal packing and 4/285 routinely prescribed antibiotics. The increase in the use of direct-vision techniques and controlled haemostasis at the time of operation may lead to a fall in the reactionary haemorrhage rate.

Secondary haemorrhage after adenoidectomy is rare. It may be due to bleeding from an aberrant ascending pharyngeal artery.⁵⁰ Unusual reactionary or secondary bleeding should raise the possibility of a clotting or coagulation defect. This will require specialist haematological advice to confirm or exclude.

Dental trauma

Damage to the teeth during adenoidectomy may be accidental due to slippage of the gag or supports. Great care is needed, particularly if the secondary incisors have erupted: the teeth are large, but the mandible immature, and it is safer to use an adult gag, which will rest lateral to the incisors. It is customary to warn parents about damage to teeth, but damage to the teeth will usually be considered negligent. Where there are loose deciduous teeth, consent should be taken preoperatively to remove these under anaesthetic to avoid the possibility of inhalation by the child during the operation or while recovering from anaesthesia.

Retained swab

It is mandatory to confirm that if swabs are used, the count is correct at the end of the operation before the gag is removed and the anaesthesia reversed. A swab may be retained either in the nasopharynx or in the laryngopharynx, hidden from the operator's view.

Nasopharyngeal blood clot

Blood may pool and clot in the nasopharynx during the procedure. The nasopharynx should be gently suctioned to clear any clot before removing the gag. Failure to do so may lead to the clot falling onto the larynx during recovery and causing potentially fatal acute airway obstruction (the 'coroner's clot').

Infection

Infection in the nasopharynx following adenoidectomy is clinically uncommon, although many parents report fever from the child in the week following surgery. Rarely, retropharyngeal and mediastinal abscess may occur as a result of trauma and secondary infection of the adenoid bed.⁵¹

Cervical spine

Nontraumatic atlantoaxial subluxation (Grisel syndrome) is rare, but associated with overuse of diathermy either for removal of the adenoid or following curettage when used

for haemostasis.⁵² Minimum power settings for diathermy should always be used.

Children with Down syndrome may have atlantoaxial instability. Traditionally, such children have plain imaging of the cervical spine prior to surgery. Vigilant attention to the child's preoperative neck position is essential.

Velopharyngeal dysfunction

Severe velopharyngeal incompetence is rare following adenoidectomy, estimated to occur in between 1:1500 and 1:10,000 procedures. It may lead to significant problems with hypernasal speech and swallowing, severe enough to cause nasal regurgitation of fluids. It is mandatory to assess the palate and uvula for submucous cleft of the palate prior to surgery as surgery often unmasks pre-existing palatal dysfunction.⁵³ Opinion is divided, and no evidence exists as to the management of a child with a bifid uvula with or without a submucous cleft about to undergo adenoidectomy. Using a direct-vision technique, it is possible to perform a partial adenoidectomy, clearing the choanal airway, but leaving the adenoid intact at the velopharyngeal junction.

Long-term velopharyngeal insufficiency is rare. In a retrospective review this occurred after 1 in 1200 adenoidectomies. Reconstructive surgery to correct hypernasal speech may be required if speech and swallowing are severely affected.⁵⁴

Regrowth of the adenoid

A cross-sectional follow-up study of children after adenoidectomy two to five years after surgery concluded that 71 percent had no residual obstructing adenoid. However, the criterion for adenoid sufficient to cause nasal obstruction was tissue occupying more than 40 percent of the nasopharynx.⁵⁵ Empirically, many surgeons may consider this significant enough to warrant further surgery.

KEY POINTS

- Adenoidal hyperplasia in childhood is common and self-limiting; mild symptoms of obstruction are not an indication for surgery.
- Significant obstructive symptoms, short of obstructive sleep apnoea, may have effects on daytime behaviour and cognitive function.
- Adenoidectomy is effective in the surgical management of children with upper airway obstruction.
- Adenoidectomy may not be effective in the management of recurrent acute otitis media.

Best clinical practice

- ✓ It is no longer appropriate to combine adenoidectomy with tonsillectomy, unless there is a specific indication for adenoidectomy [Grade C]
- ✓ Adjuvant adenoidectomy may be considered as part of the surgical management of children over the age of three years with otitis media with effusion. [Grade B]
- ✓ Routine preoperative investigations are not indicated prior to adenoidectomy for children who are ASA grade 1. [Grade C]
- ✓ Adenoidectomy under direct vision using single use instrumentation – excepting the KTP laser – is now a preferred alternative to curettage. [Grade B]

Deficiencies in current knowledge and areas for future research

For each of the following topics there is no currently available evidence at level 1, and further studies are recommended:

- Efficacy and morbidity of different techniques of adenoidectomy.
- Efficacy of adenoidectomy in the management of obstructive sleep apnoea in children.
- Efficacy of adenoidectomy in the management of chronic and recurrent acute sinusitis in children.
- The effects of adenoidectomy on the development of childhood immunity.
- The relationship between adenoidal hypertrophy and childhood rhinitis.
- The role of the adenoid in facilitating a biofilm infection in the upper respiratory tract.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words obstructive sleep apnoea, sleep-disordered breathing, child, paediatric, snoring, sleep disorders, heart failure, pulmonary hypertension, polysomnography and focussing on definitions, symptoms, sleep studies and outcomes of intervention.

DEFINITIONS AND EPIDEMIOLOGY

Obstructive sleep apnoea (OSA) is characterized by episodic partial or complete obstruction of the upper airway during sleep. This causes apnoea or cessation of breathing. Intermittent episodes of brief cessation of breathing may be physiological. An ‘apnoea’ is defined in adults as cessation of breathing for ten seconds or more. Six seconds or less may be pathological in children. The differences in sleep physiology between adults and children have bedevilled attempts to define OSA in children with the same precision as in adult medicine.^{1,2} Upper airway obstructions during sleep affect pulmonary ventilation and can lead to a drop in peripheral oxygen saturation (hypoxaemia) and retention of carbon dioxide (hypercarbia). Upper airway obstruction disrupts normal sleeping patterns by causing arousals, presumably induced by the effect of hypoxaemia and hypercarbia on the respiratory centre. It is now recognized that sleep-disordered breathing

is a spectrum of airway obstruction, and the term encompasses simple snoring, upper airway resistance syndrome (UARS) and the more severe OSA.

Simple snoring

Simple snoring is defined as snoring without obstructive apnoeas, frequent arousals or gas exchange abnormalities. It is generally considered benign although there is growing evidence that it may not be as innocuous a condition as has been believed. In addition to evidence that the secretion of growth hormone is reduced in children with simple snoring,³ cohort studies of children with habitual snoring suggest they have a higher incidence of neurocognitive disorders, with demonstrable adverse effects on quality of life. Furthermore, these effects are reversible by adenotonsillectomy, and it may be that we

need to revise our criteria for intervention in this group of children.⁴

Upper airways resistance syndrome

Upper airways resistance syndrome is a more subtle form of sleep-disordered breathing than OSA. It is characterized by partial upper airway obstruction. The frequency and severity of apnoeas is insufficient to warrant a diagnosis of OSA. UARS can lead to significant clinical symptoms as a result of night-time arousals and pulmonary hypoventilation.⁵ This disorder is more common than OSA but is often underdiagnosed.⁶ [****/***]

Obstructive sleep apnoea

OSA causes loud persistent snoring interrupted by gasping or choking episodes and silent periods which are apnoeas. It causes significant sleep disruption. This can lead to daytime neurobehavioural problems such as an increase in total sleep time, hyperactivity, irritability, bed-wetting and morning headaches.⁷ OSA may significantly affect a child and their family's quality of life.⁸ [***]

Untreated OSA can result in significant morbidity such as failure to thrive, pulmonary hypertension and right heart failure.⁹ Failure to thrive is not common in these times but children with OSA tend to have a growth spurt following adenotonsillectomy.³ Although overt right heart failure occurs less frequently, asymptomatic degrees of pulmonary hypertension may be common.¹⁰

Difficulties concerning definition mean that the exact prevalence of sleep-disordered breathing in children is unknown but may be as high as 11 percent,¹¹ and it affects between 26 and 65 percent of all children attending otolaryngology clinics in the UK.¹² OSA has a prevalence of approximately 2 percent in the paediatric population and is more common in African children.^{13,14} Sleep-disordered breathing can affect children of all ages but its peak incidence is between the ages of three and seven, when the adenoid and tonsillar lymphoid tissue is disproportionately large relative to the pharyngeal airway.¹⁵ There is an equal incidence in boys and girls but it presents earlier in boys.¹³

Factors that increase the risk of OSA in otherwise healthy children include adenotonsillar hypertrophy, family predisposition, obesity and mild craniofacial disproportion.^{11,14} OSA is also associated with a number of craniofacial syndromes and systemic diseases, in which it has a much higher incidence than in otherwise healthy children (Table 85.1). This is a result of craniofacial disproportion and the presence of coexisting upper airway hypotonia. The site of upper airway obstruction is not confined to the adenotonsillar area in these children, and requires investigation.¹⁶ [***/**]

Table 85.1 Children with increased risk of OSA.

Craniofacial syndromes	Systemic illness
Pierre Robin sequence	Cerebral palsy
Crouzon syndrome	Myotonic dystrophies
Goldenhar syndrome	Obesity
Treacher Collins syndrome	Sickle cell disease
Apert syndrome	Glycogen storage disorder
Down syndrome	Achondroplasia
Hunter syndrome	
Velocardiofacial syndrome	
Beckwith–Wiedemann syndrome	

MECHANISM OF SLEEP-DISORDERED BREATHING AND PHYSIOLOGICAL AFFECTS

Breathing against a partially or completely obstructed upper airway causes the clinical signs of sleep-disordered breathing, which include loud snoring, increased respiratory effort with flaring of the nostrils, suprasternal and intercostal recession. Complete obstruction of the pharyngeal airway, as in OSA, leads to silent periods followed by choking or gasping as the child rouses from sleep to re-establish their airway.

Partial (hypopnoea) or complete upper airway obstruction (apnoea) during sleep can lead to hypoxia and hypercarbia. The degree of hypoxia is influenced by the duration of the apnoeic event, the condition of the cardiopulmonary system and whether a coexisting neuromuscular disorder is present. Hypoxia leads to a rise in sympathetic output causing peripheral vasoconstriction, which results in tachycardia and a rise in blood pressure. Changes in the pulse and blood pressure reflect increased sympathetic activity and are markers of subcortical arousal. They correlate directly with the severity of the sleep-disordered breathing and can be used to quantify it. The diastolic blood pressure during rapid eye movement (REM) sleep shows a significant correlation with the number of apnoeas and hypopnoeas.¹⁷ The pulse transit time is a noninvasive marker of blood pressure. It is the interval between the R wave on an electrocardiogram (ECG) and the arrival of the pulse at the finger. The pulse transit time is increased in the presence of increased respiratory effort and decreased in the presence of tachycardia associated with arousal. It is a more sensitive measure of obstructive events than visible electroencephalogram (EEG) arousals found on full polysomnography recording.¹⁸

Upper airway obstructive events are terminated by these subcortical arousals. The child is unaware of these but they may occur several hundred times a night. Repeated arousals greatly disturb a child's sleep pattern which can lead to changes in behaviour and concentration ability as well as having general effects on a child's quality of life.^{4,5} The rise in pulmonary blood pressure as a result

of increased sympathetic activity leads to transient pulmonary hypertension. Long-standing sleep apnoea can result in irreversible pulmonary hypertension and if sustained this will lead to right heart failure and cor pulmonale.⁹

A gradual, improved understanding of these physiological changes that occur during sleep has helped clinicians identify the parameters that need to be measured to ascertain the severity of the sleep-disordered breathing. Full polysomnography is the 'gold standard' investigation for sleep disorders. It can differentiate sleep-disordered breathing from other types of sleep disorder, such as periodic leg movement and narcolepsy. However, if sleep-disordered breathing is suspected, full polysomnography can be substituted by less elaborate sleep studies which measure and analyze pulse rate and oxygen saturation complemented with video and sound recordings of the sleeping child, for example the Visi-LabTM analysis. [***]

CLINICAL SYMPTOMS

The cardinal symptom of sleep-disordered breathing in children is snoring. Severe sleep apnoea with loud, persistent snoring is more likely in younger children. Children with significant obstruction sweat during sleep, particularly in the nuchal area, and have a tracheal tug and intercostal recession with loud stertorous breathing. Children who have repeated apnoeas leading to arousals are very restless at night, often adopting unusual sleeping positions in an attempt to relieve their upper airway obstruction. They may also complain of very dry mouth and morning headaches. The high intrathoracic pressures generated in a child with OSA may cause oesophageal reflux leading to unexplained regurgitation or vomiting during sleep.

A further commonly witnessed symptom is choking episodes. This is best enquired about by imitating a guttural noise, as parents are often not aware of why the noise is being created. Parents often describe witnessed apnoeas as momentary breath holding. Most parents, if asked directly, will deny that their child stops breathing at night. This can lead to an underestimation of the presence of sleep apnoea if the clinical history is not taken with enough attention to detail.

True daytime somnolence as described in adults is unusual in children. Hyperactivity is more common and affected children are often irritable on waking.⁷

It is also important to identify whether the affected child has associated rhinosinusitis as this can exacerbate their sleep-disordered breathing. Rhinosinusitis may be allergic, infective or structural in origin. Medical treatment of this will improve the child's sleep-disordered breathing. Similarly, pulmonary disease may also exacerbate sleep apnoea by causing increased work in breathing requiring higher intrathoracic pressures. The child with severe OSA has chronic hypoventilation at night, which

may lead to pulmonary atelectasia. These children develop a cough with most viral upper respiratory tract infections. A history of previous hospital admission with acute airway compromise heralds an increased risk of complications following surgical intervention.

CLINICAL EXAMINATION

Clinical examination should include a full ENT examination, height and weight measurements and cardiopulmonary examination. Sleep-disordered breathing is more common in the obese child. Conversely, sleep-disordered breathing in a child can cause failure to thrive or a decrease in growth rate.

Subtle craniofacial disproportion should be looked for. Children with a triangular chin, steep mandibular angle, retrognathia, narrow high-arched palate and long soft palate are likely to have sleep-disordered breathing. Mouth breathing indicates nasal obstruction, and examination within the nose should look at the structure of the septum and the quality of the nasal lining for the presence of rhinosinusitis. Many children with sleep-disordered breathing are daytime mouth breathers and therefore the presence of chronic mouth breathing should raise the index of clinical suspicion.

Hyporesonant voice points to enlarged adenoids. In some children it may be possible to perform nasendoscopy with a fiberoptic endoscope to ascertain the size of the adenoid pad and extent of choanal obstruction (**Figure 85.1**). Examination within the oral cavity should exclude a submucous cleft and be used to document the size of the tonsils (**Figure 85.2**). Although most children with OSA have large tonsils, studies show that there is little correlation between the size of the tonsils and the severity of sleep-disordered breathing.¹⁹ Small tonsils can cause upper airway obstruction if there is excessive medialization of the lateral pharyngeal walls during sleep. This can be the result of poor neuromuscular control of the pharyngeal airway, as in cerebral palsy, and previous cleft palate repair. Alternatively, a very large adenoid pad can cause a marked reduction in the calibre of the airway even in the presence of relatively small tonsils. Also, the site of upper airway obstruction is not necessarily adenotonsillar, particularly in syndromic children.¹⁶

Daytime stertorous breathing is indicative of severe sleep apnoea, as is growth retardation, which has been shown to be due to a reduction in growth hormone secretion.^{3,20} The presence of broken veins on the face indicates raised venous pressure in the face due to upper airway obstruction. Pectus excavatum can result from long-standing intercostal recession during sleep. The presence of noisy breathing, other than stertor, should alert the clinician to the presence of possible distal airway pathology.

Clinical history and examination will confirm the presence of sleep-disordered breathing but cannot reliably

distinguish between children with simple snoring and OSA. The clinical history will overdiagnose mild sleep apnoea and under diagnose severe OSA. There are a number of reasons why the history can be misleading. Children with OSA experience most of their obstruction during rapid eye movement sleep (REM sleep), which occurs primarily in the early hours of the morning when parents are not observing them.²¹ Children with UARS have a pattern of partial upper airway obstruction which leads to gas exchange abnormalities rather than true apnoeas and may be underreported.⁶

The history and clinical examination will enable the clinician to decide which child needs further investigation but it cannot always determine the need for intervention. An accurate diagnosis is, therefore, needed to ensure appropriate treatment, avoid unnecessary treatment and identify children at risk of developing complications of treatment. [***/**]

INVESTIGATIONS

Investigations are needed in paediatric sleep-disordered breathing to:

- identify children who are at increased risk of the complications associated with sleep-disordered breathing;
- avoid unnecessary intervention in children with simple snoring;
- identify children who are at increased risk of complications following surgical intervention;
- identify the site of upper airway obstruction in a child with sleep-disordered breathing.

Sleep studies

The clinical history and examination will identify most children with sleep-disordered breathing but are not sensitive enough to define severity or differentiate between simple snoring and more severe forms of sleep-disordered breathing. Symptom questionnaires designed to complement the clinical history are good at identifying more severe cases.²² However, more objective evidence of the severity of sleep-disordered breathing may be sought.

Pulse oxymetry is a screening tool. It relies on indirect measurement of the arterial oxygen saturation using a probe, usually applied to the finger.²³ It is minimally invasive, and can be undertaken in a child's home if a recording device is available. **Readings above 97 percent exclude serious hypoxia or hypercarbia.**²⁴ **Readings below 87 percent may suggest coexistent cardiac or bronchopulmonary disease.** Between these two extremes it gives little information as to the severity of the sleep apnoea and will miss apnoeic episodes not associated with oxygen desaturation.²⁵ However, despite these shortcomings, pulse

oxymetry does provide some information regarding the severity of OSA, as it will identify severe cases with significant desaturations. It has a high positive predictive value of approximately 97 percent. It is not so helpful in assessing mild-to-moderate OSA, with a low negative predictive value of approximately 47 percent.²⁶

One step up from simple pulse oxymetry is a ‘mini-sleep’ study system. These systems combine pulse oxymetry with video footage and sound recording. Computer software measures movement from the movement detector, snoring from the microphone and analyzes the pulse oxymeter output. The best known is the Visi-Lab. Increased work of breathing (hypopnoeas) and apnoeic episodes without significant oxygen desaturation can be detected using this form of sleep study. A rise in pulse rate associated with a desaturation signifies an arousal and corresponds to the number of apnoeas and hypopnoeas. This data is more useful in adult sleep medicine as age-appropriate criteria for children are not yet standardized.²

The American Sleep Apnoea Association currently grades sleep apnoea in the form of the apnoea/hypopnoea index. This is the total number of apnoeas and hypopnoeas divided by the total sleep time, which gives an index per hour (Table 85.2).

The gold standard investigation for sleep disorders is full polysomnography. This monitors EEG activity, chest and abdominal movement, oxygen saturation, nasal or oral airflow, end tidal carbon dioxide and continuous ECG recordings. Video monitoring during polysomnography is also helpful but is not standard. Full polysomnography identifies EEG arousal and provides an apnoea/hypopnoea index. It also differentiates between different types of sleep disorder and identifies central apnoeas.

Although ideal, full polysomnography is detailed and expensive and cannot be provided for every child suspected of suffering with sleep-disordered breathing. There is, therefore, the need for rationalization of sleep study investigations depending on the clinical needs of the child (Table 85.3). [Grade B]

Sleep nasendoscopy

Although polysomnography is invaluable and essential in documenting the severity of OSA it provides no information concerning the site of upper airway obstruction.

Table 85.2 The apnoea/hypopnoea index.

Apnoea/Hypopnoea index (per hour)	Level of OSA
5–20	Mild
20–40	Moderate
> 40	Severe

Table 85.3 Recommendations for investigation.

Which child?	Type of investigation
Healthy child >3 years	No investigations necessary
Healthy child >3 years with increased risk of postoperative respiratory complications	Chest x-ray and ECG Visi-Lab study
Healthy child <3 years	Chest x-ray and ECG Overnight pulse oxymetry Visi-Lab study
Healthy children with: obesity; small tonsils; mild cranofacial disproportion	Sleep nasendoscopy Microlaryngobronchoscopy Post-intervention sleep study
Neuromuscular disease	Full polysomnography Sleep nasendoscopy Post-intervention sleep study

Ascertaining the site of upper airway obstruction is essential in children with obesity, small tonsils or craniofacial disproportion and in those with syndromes and neuromuscular disease. The reason for this is that the site of upper airway obstruction is not necessarily adenotonsillar and may be anywhere from the palate to the supraglottis.¹⁶ The site of upper airway obstruction varies not only between children with different syndromes but also between children with the same syndrome.

Direct visualization of the upper airway using a flexible fibreoptic endoscope in children with obstructive ‘awake’ apnoea has proved to be very accurate in diagnosing the site of airway obstruction which occur during sleep.²⁷ It has also become the first-line investigation in the management of children with stridor.

Sleep endoscopy using a flexible fibreoptic endoscope (sleep nasendoscopy) was first described by Croft and Pringle,²⁸ and is routinely used to assess the site of snoring and airway obstruction in adults. In children, sleep nasendoscopy can be performed with the child breathing spontaneously a mixture of halothane and oxygen. This is thought to provide a relaxation of the upper airway musculature that mimics natural sleep.¹⁶

Sleep nasendoscopy should be performed in the operating theatre with a skilled paediatric anaesthetist and full cardiopulmonary monitoring. The sites of upper airway obstruction can be documented using a four-level classification system (Figure 85.3). The site or level at which the upper airway obstruction is occurring will define the intervention that is needed to correct it. To classify the site of obstruction the upper aerodigestive tract can be divided into the following four functional levels:

- 1. level 1 or adenoid pad and velopharyngeal obstruction;

© Hodder Arnold / Scott-Brown 7E

Figure 85.3 A classification system for documenting the findings at sleep nasendoscopy. The photographs show the endoscopic view of the obstruction at each level from 1 to 4.

2. level 2 or tonsillar obstruction;
3. level 3 or tongue base obstruction;
4. level 4 or supraglottic obstruction. [Grade B]

Rigid laryngobronchoscopy

Formal rigid laryngobronchoscopy should be performed in the assessment of syndromic children with complex obstructive breathing and in children who have a history of prematurity and prolonged inhalation on a neonatal intensive care unit.¹⁶ It is important to exclude the presence of pathology distal to the glottis that may be exacerbating the upper airway symptoms, for example subglottic stenosis, tracheomalacia, innominate artery compression, bronchomalacia or vascular rings. The incidence of distal airway pathology is higher in Down syndrome patients than in the general population. In one

study, approximately 28 percent of children with Down syndrome and sleep-disordered breathing were found to have laryngeal or tracheal abnormalities on rigid laryngobronchoscopy.²⁹ The incidence of distal airway pathology in other syndromes is unknown but laryngeal abnormalities have been described in Goldenhar syndrome,³⁰ and major aortic arch abnormalities in velocardiofacial syndrome can cause tracheal compression.³¹ [Grade C]

Imaging

A chest x-ray is mandatory in all children with moderate-to-severe OSA. It will identify pulmonary hypertension and right ventricular hypertrophy causing cardiomegaly. A chest x-ray also detects atelectasia caused by chronic hyperventilation. A lateral x-ray of the post-nasal space is

useful in ascertaining adenoid size in children in whom flexible nasendoscopy has not been possible (Figure 85.4). Cardiac echocardiography is needed to exclude pulmonary hypertension or right-sided heart failure if EEG or chest x-ray are suggestive. Cardiac catheterization may then be necessary to measure pulmonary venous pressures in severe cases. Cephalometry, fluoroscopy and dynamic magnetic resonance imaging have been used in the assessment of OSA in children but have a limited role.³² [Grade B]

RECOMMENDATIONS FOR INVESTIGATIONS

In otherwise healthy children over three years old with a history compatible with OSA and large tonsils and adenoids on examination, further investigation of their sleep-disordered breathing is not essential prior to adenotonsillectomy unless they are suspected of having severe OSA. In such cases, pulse oxymetry or a Visi-Lab study should be undertaken. A chest x-ray should be performed to look for atelectasia and an ECG to look for signs of right ventricular hypertrophy or pulmonary hypertension.

Otherwise healthy children under three years of age and other 'at risk' children (listed in Table 85.1) are likely to have severe OSA and should have a chest x-ray, ECG and a Visi-Lab study.

© Hodder Arnold / Scott-Brown 7E

Figure 85.4 A lateral soft tissue x-ray of the head and neck of a three-year-old child with significant obstruction of the nasopharyngeal airway by enlarged adenoids.

Children who are clinically obese, have small tonsils and adenoids on examination or have mild craniofacial disproportion need further investigation to ascertain the severity of the sleep-disordered breathing and the site of upper airway obstruction. This is because adenotonsillectomy may not be curative, and an outcome measure is needed. A Visi-Lab study would provide this. Sleep nasendoscopy is needed to confirm the site of upper airway obstruction prior to adenotonsillectomy so that upper airway obstruction at other sites can be identified and appropriate intervention can be planned.

Syndromic children and those with neuromuscular disease need investigation with full polysomnography as they are likely to have associated central apnoeas and ongoing problems throughout their childhood despite intervention. Sleep nasendoscopy is needed to confirm the site of upper airway obstruction in these children if site-specific treatment is planned. [Grade B] (See also Table 85.3.)

TREATMENT

Medical treatment

Children with OSA who present with mucopurulent nasal discharge should have this treated, as it will improve their nocturnal symptoms. Treatment should consist of a four-to six-week course of systemic antibiotics combined with topical intranasal steroids. These children should be tested for sensitivity to airborne allergens that may be irritating the mucosal lining of the nose and paranasal sinuses.

Children with severe OSA, who have a persistent cough or signs of pulmonary atelectasia on chest x-ray, should be given systemic antibiotics and steroids prior to a general anaesthetic. This will help clear bronchial secretions and improve pulmonary function, thereby reducing the risk of postoperative respiratory failure. [Grade D]

CONTINUOUS POSITIVE AIRWAY PRESSURE

Continuous positive airway pressure (CPAP) provides continuous insufflation of the nasopharyngeal airway during sleep, thereby splinting the airway and maintaining its patency. It is usually delivered via a nasal mask and has to be used every night on an indefinite basis. It is a long-term therapy and requires frequent assessment of compliance and efficacy by a paediatric sleep physician. The CPAP pressures are titrated using polysomnography in the sleep laboratory and are periodically adjusted thereafter. Recent work with autotitrated CPAP in children has shown promise.¹ Patients such as the obese child, syndromic children and children with cerebral palsy may not be considered surgical candidates and may benefit from long-term CPAP.³³ CPAP can be started from

birth and is well tolerated in older children. CPAP can also be used prior to planned surgical intervention in cases of severe OSA to minimize postoperative risk by improving pulmonary ventilation. [Grade B]

NASOPHARYNGEAL AIRWAY

Pharyngeal airway obstruction may be dramatically relieved with the use of a nasopharyngeal airway. This is of particular use in the newborn and in the first few months of life. It has been traditionally used in children with Pierre Robin sequence but also has a role in children with Apert and Crouzon syndrome. The length of the nasopharyngeal airway can be tailored according to the site of airway obstruction. In Pierre Robin sequence the tip of the nasopharyngeal airway needs to lie just above the epiglottis and in Apert's syndrome to the free edge of the soft palate. Many children with Pierre Robin sequence improve in the first few months of life, and the nasopharyngeal airway may be sufficient treatment of their upper airway obstruction. A sleep study can be performed with the tube *in situ* to assess its effectiveness, and another study performed on planned removal of the airway a few months later to assess progress. [Grade C]

MANDIBULAR ADVANCEMENT SPLINTS

Mandibular advancement splints have been used in some paediatric patients with OSA who cannot tolerate CPAP and are not suitable for surgical intervention. However, a recent study in adults has shown that the symptom relief and improvement in sleep parameters was better with CPAP than with splints.³⁴ [Grade B]

Surgical treatment

Adenotonsillectomy is the treatment of choice for otherwise healthy children suffering with sleep-disordered breathing. The results of surgery are an improvement in nocturnal hypoxia, behaviour, quality of life and growth rate.^{1, 2, 3, 4, 5, 7} [****/***] Polysomnography performed before and after adenotonsillectomy in children with sleep-disordered breathing has demonstrated a universal improvement in their apnoea/hypopnoea index and an abolition of OSA in approximately 90 percent of cases.³⁵ However, this means that 10 percent of apparently healthy children continue to have OSA after adenotonsillectomy. This group consists of the clinically obese, those with mild craniofacial disproportion, deviated nasal septum, and those with small tonsils on examination. Adenotonsillectomy should still be considered in these children as it can have a satisfactory outcome in some cases.³⁶ Performing sleep nasendoscopy at the induction of anaesthesia will identify the site of the upper airway obstruction, which may be at more than one level and thus help with the long term management.¹⁶

The results of adenotonsillectomy in children with Down syndrome, cerebral palsy and craniofacial abnormalities are not so encouraging. Recent studies show that between 54 and 100 percent of children with Down syndrome have OSA on polysomnography and the results of adenotonsillectomy are disappointing.³⁷ Other surgical treatments for OSA in Down syndrome include tonsillar pillar plication after tonsillectomy, midface advancement, uvulopalatopharyngoplasty (UVPP), anterior tongue reduction and hyoid suspension. Even with these forms of surgery an improvement in the child's symptoms is seen in only approximately 70 percent of cases, and deaths from upper airway obstruction are still not uncommon.³⁸

Children with cerebral palsy also have much a higher incidence of OSA and sleep-disrupted breathing than age-matched controls when investigated with polysomnography.³⁹ Adenotonsillectomy in this group is rarely curative and UVPP has been advocated as an alternative to tracheostomy.⁴⁰ The difficulty with predicting outcome with UVPP is the multifactorial nature of the airway obstruction, notably the presence of central apnoeas, the general hypotonia of the pharynx, the poor gag reflex, salivary pooling and the multisegment collapse of the upper airway. These factors contribute to a progression from OSA to obstructive awake apnoea and noisy daytime breathing. Laser supraglottoplasty has been used to treat selected cases, with resolution of the noisy breathing (Figure 85.5). Other treatments tried as an alternative to tracheostomy include hyoid suspension, mandibular advancement and tongue reduction.

Children with craniofacial syndromes can be treated with a nasopharyngeal airway or tracheostomy until formal midface advancement is performed at about five years of age. Distraction osteogenesis has shown some early promising results and can be performed at a much earlier age (see Chapter 78, Craniofacial anomalies: genetics and management).⁴¹ [Grade B/C]

TREATMENT OPTIONS ACCORDING TO THE LEVEL OF OBSTRUCTION SEEN AT SLEEP NASENDOSCOPY

Depending on the level of obstruction seen at sleep nasendoscopy, the following are treatment options.

- Level 1 obstruction (velopharyngeal obstruction) is relieved by adenoidectomy or UVPP.
- Level 2 obstruction (tonsillar) is relieved by tonsillectomy.
- Level 3 obstruction (tongue base) can be relieved with the use of nasopharyngeal airways, glossopexy, mandibular advancement splints or CPAP.
- Level 4 obstruction (supraglottic) is due to collapse of the supraglottic tissues and manifests in its commonest form as laryngomalacia. It is a common finding in children with cerebral palsy who have upper airway obstruction. The treatment of

Figure 85.5 (a) An endoscopic view of the crowded supraglottis in a child with cerebral palsy. (b) The endoscopic view after dividing the aryepiglottic folds and vaporizing the redundant soft tissue overlying the arytenoid cartilages with a carbon dioxide laser.

obstruction at this level can be site specific in the form of **laser supraglottoplasty** or **anterior epiglottopexy**. A tracheostomy will be curative if the more localized procedures are insufficient. [Grade B]

POSTOPERATIVE COMPLICATIONS AND REDUCTION OF PERIOPERATIVE RISK

The potential surgical complications following adenotonsillectomy include pain, which causes poor oral intake, and haemorrhage. More worrying is that up to 20 percent of children who undergo adenotonsillectomy for OSA develop postoperative respiratory failure.⁴² For this reason, otherwise healthy children undergoing adenotonsillectomy for moderate to severe OSA should not be booked as day cases.

Identified risk factors for the development of postoperative complications in otherwise healthy children are:

- severe OSA;
- a history of acute airway compromise;
- young age (less than three years);
- cardiac complications;
- failure to thrive;
- obesity;
- prematurity.

Children with craniofacial syndromes, neuromuscular diseases and systemic illnesses are also at increased risk of postoperative respiratory complications (**Table 85.1**).

These 'at risk' children may need to be admitted 24 hours prior to an anaesthetic for the administration of systemic steroid to reduce pulmonary atelectasia. They should also undergo pulse oxymetry the night before a general anaesthetic and for one or two nights postoperatively to document the severity of oxygen desaturations, even though a previous sleep study will have been carried out. Postoperative admission to an intensive care unit should be considered for all high-risk children, especially those who will have persistent OSA despite the planned surgical intervention. Systemic steroids and antibiotics, nebulized bronchodilators and chest physiotherapy are needed in the perioperative period if the child has audible crepitations on chest examination. [Grade D]

Children with OSA are very sensitive to narcotic analgesia, which has a significant detrimental effect on their respiratory drive.⁴³ Narcotics should be completely avoided in the perioperative period in any 'at risk' child. An experienced paediatric anaesthetist will be needed to provide the general anaesthetic. Following surgery, the endotracheal tube should not be removed until the patient has fully recovered from the anaesthetic, so as to minimize the risk of upper airway obstruction.

Children with Down syndrome or cerebral palsy may need to be intubated in intensive care for the first 24 hours postoperatively until surgical oedema has settled. Alternatively, a nasopharyngeal prong can be used to stent the soft palate following UVPP or adenotonsillectomy in these children. Systemic steroids should be continued postoperatively for the first 24 hours to help with surgical oedema and pulmonary atelectasia. They have also been shown to reduce postoperative pain following tonsillectomy.⁴⁴ Patients who are on CPAP preoperatively can restart this immediately postoperatively and then can be weaned from it if the surgery is deemed successful. [Grade B]

LONG-TERM POSTOPERATIVE FOLLOW-UP

All patients should have clinical follow-up following initial treatment to document improvement or resolution

of their symptoms. Children diagnosed as having mild or moderate sleep apnoea who have complete resolution of their symptoms do not require post-intervention sleep studies.

Children who continue to have symptoms, had severe OSA on presentation or are in the 'high-risk' group should have a post-intervention sleep study (**Table 85.3**). The sleep study should be performed at least six weeks after surgery to ensure that the upper airway remodelling is complete. [Grade B]

CONCLUSION

Before paediatric OSA was recognized, children affected would present with severe failure to thrive and growth retardation, right-sided heart failure, cor pulmonale, permanent neurological damage, behavioural disturbance, hypersomnolence and developmental delay. Since the advent of paediatric sleep laboratories in the 1970s, OSA has been a widely recognized problem commonly encountered by paediatricians, otolaryngologists, anaesthetists and neurologists.

Adenotonsillectomy provides a cure in the great majority of children with OSA but in syndromic children and those with neuromuscular diseases it can present a real therapeutic challenge. Such children need treatment decisions to be made in collaboration with paediatric, sleep physician and anaesthetic colleagues and the parents or carers, so as to arrive at the most acceptable treatment option.

KEY POINTS

- Pathological sleep-disordered breathing occurs in approximately 10 percent of the paediatric population.
- Adenotonsillectomy cures or improves sleep apnoea in 90 percent of children.
- Sleep-disordered breathing can cause neurobehavioural and cardiac complications.
- Children at increased risk of OSA have been identified.
- Sleep studies provide objective measure of the severity of sleep-disordered breathing.
- Sleep nasendoscopy can identify the site of upper airway obstruction.
- Children at increased risk of respiratory failure following surgical intervention have been identified.
- Children with persistent symptoms after intervention need follow-up sleep studies.

Best clinical practice

- ✓ Snoring children should be screened for the presence of sleep-disordered breathing.
- ✓ 'At risk' children need preoperative sleep studies and careful perioperative management to minimize the possibility of postoperative respiratory failure.
- ✓ Syndromic children and those with neuromuscular disease pose a significant management challenge and need a multidisciplinary approach.
- ✓ The site of upper airway obstruction should be investigated with sleep nasendoscopy if there is any doubt that it may not be adenotonsillar.
- ✓ Persistent symptoms of OSA after intervention need follow-up with a postoperative sleep study.

Deficiencies in current knowledge and areas for future research

- Understanding of the natural history of sleep-disordered breathing. There is concern that children with OSA may go on to develop adult sleep-related breathing disorders. This tendency may be reversed by early adenotonsillectomy.
- Understanding of the clinical relevance of simple snoring. It may be that simple snoring is more serious than currently thought.
- Accurate prevalence data for sleep-disordered breathing and age-appropriate diagnostic criteria.
- Understanding of the mechanism of arousal and how it leads to daytime symptoms.
- Development of standardized perioperative care designed to reduce postoperative respiratory failure.

Management of acute airway obstruction	1123	References	1125
Key points	1124		

SEARCH STRATEGY

The author has a personal bibliography of key papers on paediatric airway obstruction. This was supplemented with successive searches of Medline using the following strategies: title or text word stridor and key words child, laryngomalacia, tracheomalacia; vocal cord palsy and child, vocal fold palsy and child, vascular ring and child, congenital subglottic stenosis and child, laryngotracheobronchitis and child, bacterial tracheitis and child, extubation and child, biphasic stridor, mediastinal mass and airway obstruction and child. The rationale for most interventions in childhood stridor is based on the current practices of experienced clinicians. Few treatments have been subjected to controlled trials. Hence, apart from steroid therapy in croup, recommendations in this chapter are Grade C and D.

INTRODUCTION

This chapter discusses the diagnostic accuracy of history and examination. It then reviews the usefulness of special investigations. This is an overview so that the clinician can be directed to the appropriate chapter for detailed information on specific conditions. The general principles of management of the acutely stridulous child are presented.

Definitions

Turbulent flow due to partial obstruction of the airway gives rise to abnormal or unwanted noise. Obstruction of the small intra-thoracic airways, such as occurs in bronchial asthma, is termed 'wheezing'. Noise originating in the larynx or trachea is typically high-pitched and termed 'stridor'. The low-pitched snoring type of noise made by naso- and oropharyngeal obstruction is usually termed 'stertor'. This type of noise can occasionally be

produced by the supraglottic larynx. A rigid differentiation between stridor and stertor is not only artificial but can wrongly limit the differential diagnosis (Tables 86.1, 86.2 and 86.3).

The challenge of managing a stridulous child

A child labelled as 'congenital stridor' may, rarely, have a more sinister diagnosis. History and examination are insufficient for a firm diagnosis. Deciding which patients to investigate is sometimes difficult. Even after non-invasive investigations such as imaging there may still be a number of possible diagnoses. Flexible endoscopy in the office is useful but gives little or no information beyond the glottis.

The definitive diagnostic technique of laryngotracheo-bronchoscopy (LTB) requires an experienced team of surgeon, anaesthetist and nursing staff. Both equipment and expertise are now highly specialized and are not available in all institutions.

Table 86.1 Nasopharyngeal causes of airway obstruction.

Common		Acquired		
Neonates	Children	Neonates	Children	Congenital
Neonatal rhinitis	Allergic rhinitis	Syphilis	Allergic rhinitis	Choanal atresia
Choanal atresia/stenosis	Adenoiditis	Neonatal rhinitis	Adenoiditis	Choanal stenosis
Craniofacial abnormalities	Adenotonsillar hypertrophy		Adenotonsillar hypertrophy	Mid-nasal stenosis
Micrognathia	Foreign bodies		Foreign bodies	Piriform aperture stenosis
			Nonallergic rhinitis	Nasal glioma
			Nonallergic rhinitis with eosinophilia (NARES)	Encephalocoele
			Retropharyngeal abscess	Meningocoele
			Glandular fever	Nasopharyngeal mass
			Ludwig's angina	Hairy polyp/teratoma
			Thermal and caustic burns

				Cystic hygroma
				Lingual thyroid

Table 86.2 Laryngeal causes of airway obstruction.

Common		Acquired		
Neonates	Children	Neonates	Children	Congenital
Laryngomalacia	Croup	Intubation trauma	Epiglottitis	Laryngomalacia
Intubation trauma	Haemangiomas	Surgical trauma, e.g. laser	Croup	Posterior laryngeal cleft
Reflux laryngitis	Papillomatosis	Laryngotracheal stenosis	Bacterial tracheitis	Vallecula cyst
Laryngotracheal stenosis	Intubation trauma	Arytenoid fixation	Hereditary angioedema	Laryngeal cysts
Vocal cord palsy	Vocal cord palsy	Reflux laryngitis	Epidemolysis bullosa	Webs
	Papillomatosis		Foreign bodies	Laryngeal atresia
			Dislocated arytenoid	Laryngotracheal stenosis
			Intubation trauma	Arytenoid fixation
			Fracture	Vocal cord palsy
			Caustic and thermal burns	
			Haemangiomas	
			Cystic hygroma	
			Papillomatosis	
			Rhabdomyosarcoma	
			Wegener's	

In the acute situation the infant airway can deteriorate rapidly. In a specialized unit this is rarely a problem with experienced anaesthetists to intubate and surgeons to perform the rare emergency tracheotomy. In a paediatric ward or emergency room, rapid deterioration can prove a real challenge.

ASSESSMENT

Stridor is the noise from a narrowed airway. The aim of the history, examination and special examinations is to determine not only the site and cause of the obstruction (the diagnosis) but also its effect on the airway (the

Table 86.3 Tracheal causes of airway obstruction.

Common		Acquired		
Neonates	Children	Neonates	Children	Congenital
Tracheobronchomalacia	Foreign bodies	Post intubation and endoscopy	Laryngotracheitis	Stenosis
Tracheal stenosis	Tracheal stenosis	Tracheal stenosis	Bacterial tracheitis	Atresia
Vascular compression		Reflux tracheitis	Foreign bodies	Trapped first tracheal ring
			Localized malacia secondary to a tracheostomy or TEF repair	Complete cartilage rings
			Thyroid	Micro (stovepipe) trachea
				tracheal cysts
			Cystic hygroma	Haemangiomata
			Mediastinal tumours	Tracheobronchomalacia (with tracheo-oesophageal fistula)
				Vascular compression
				Aberrant innominate
				Pulmonary artery sling
				Double aortic arch

severity). It is important to consider the effect of airway obstruction on feeding, sleep, exercise and growth.

History

PERINATAL HISTORY

The obstetric and perinatal history are often relevant. This is particularly true if the child was born prematurely and required ventilation. Few neonates over 32 weeks' gestation will require ventilation for respiratory distress syndrome. Ventilation is the norm for those delivered at 28 weeks or earlier, even with the administration of surfactant. Neonates admitted even for short periods to intensive care or special care baby units (SCBU) may have had endotracheal intubation without the parents volunteering this important information. Beware the term 'intubation', as this may be mistaken for the passage of nasogastric tubes or even for nasal and oral mucus extraction.

Stridor which is present at birth, i.e. with the child's first breath, is unusual. This generally denotes a fixed congenital narrowing such as a laryngeal web, subglottic stenosis or tracheal narrowing.¹ Dynamic conditions such as laryngomalacia become evident in the first few weeks of life. The stridor in congenital vocal cord palsy is often present immediately post-partum suggesting that it may be more an incoordination than a true paralysis. A gradual increase in severity of stridor or airway compromise implies growth of an obstruction which may be luminal as in a subglottic haemangioma or extrinsic as with a mediastinal mass.

PATTERN OF STRIDOR

Stridor is seldom constant. Any diurnal or other variation can help pinpoint the cause, though asking parents about the timing of stridor in the respiratory cycle is seldom profitable. Typically, laryngomalacia is better with the child at rest and asleep but made worse by crying, feeding and when the child is distressed. Airway obstruction with the baby supine can occur with a pedunculated laryngeal mass but more often is due at least in part to a degree of supralaryngeal obstruction such as micrognathia and resultant tongue base occlusion. Improvement in the airway with crying occurs in gross nasal obstruction such as bilateral choanal atresia.

ASSOCIATED FEATURES

Airway obstruction produces a number of associated symptoms (Table 86.4) alongside stridor including recession, apnoeas, cyanosis, 'dying spells', dyspnoea, tachypnoea, cough and hoarseness. Recession, even if quite severe, can be missed by parents but is a clear sign of inspiratory obstruction. Apnoeas with cyanosis are typical of severe tracheobronchomalacia and are sometimes termed 'dying spells'. Parents will usually attempt resuscitation if these are severe. It is often unclear how many of these attacks are otherwise self-limiting. Tachypnoea and dyspnoea are not limited to upper airway obstruction but a clear description of exertional dyspnoea in an older child provides a useful functional assessment of severity. Cough is typical of tracheo-oesophageal fistula and tracheomalacia and is rarely due to 'infant asthma'. Hoarseness clearly suggests a laryngeal

Table 86.4 Symptoms associated with varying causes of airway obstruction.

Symptoms	Typical diagnoses	Example
Stertor	Nasopharyngeal obstruction	Neonatal rhinitis
Inspiratory stridor	Laryngeal and subglottic obstruction	Laryngomalacia, subglottic stenosis
Biphasic stridor	High/mid tracheal obstruction	Tracheomalacia/stenosis
Prolonged expiratory phase	Tracheal and bronchial obstruction	Tracheobronchomalacia or stenosis
Cough	TEF Vocal cord palsy Cleft larynx Foreign body Tracheomalacia Reflux	
Aspiration	TEF Vocal cord palsy Cleft larynx	
Hoarseness	Laryngeal lesion	Vocal cord palsy, papilloma
Acute airway obstruction	Retropharyngeal abscess Tonsillitis Glandular fever Foreign bodies Epiglottitis Croup Bacterial tracheitis	
Dysphagia and feeding difficulties	Epiglottitis Tonsillitis Retropharyngeal abscess	Feeding affected with many causes of severe airway obstruction and aspiration
Apnoeas	Tracheobronchomalacia	
Dying spells	Reflex apnoea	

lesion such as laryngeal papillomatosis but is also seen in vocal cord palsy.

FEEDING HISTORY

Feeding is closely connected with breathing, particularly in the infant. An accurate picture of the feeding pattern must be obtained. Breast-fed babies with airway obstruction will characteristically ‘come up for air’; bottle-fed babies may require thickened feeds or a ‘slow teat’ (i.e. one with small holes). Aspiration suggests a vocal cord palsy, tracheo-oesophageal fistula or rarely a cleft larynx. Significant repeated aspiration may be associated with recurrent chest infections. Regurgitation (‘possetting’) is common in neonates and by itself may not represent significant gastro-oesophageal reflux. The end result of poor feeding may just be slow feeding which troubles the mother more than the child or there may be failure to thrive with demonstrably poor weight gain. As laryngomalacia is common, it is important not to assign failure to

thrive to this without first having considered and excluded other causes.

GENERAL MEDICAL CONDITIONS

Enquiry into the general medical history may explain a vocal cord palsy occurring as a result of neurological disease or cardiac surgery or may suggest vascular compression associated with congenital cardiac disease. Finally, ask the parents about the presence of any birthmarks, as they may be associated with a subglottic haemangioma.

ACUTE OBSTRUCTION

In acute airway obstruction the history is taken simultaneously with the examination and resuscitation. Take particular note of any possible foreign body ingestion or concurrent illness. Rapid progression of airway obstruction typically occurs in acute infection and in foreign body inhalation.

Examination

OBSERVATION

Observing the child at rest before proceeding to formal examination provides not only an initial assessment of the degree of respiratory distress and the characteristics of any stridor but also gives time to gain the child's confidence. The characteristics of the stridor need to be observed as well as the effects of airway obstruction such as recession. Abnormal voice, wheeze or coughs are useful localizing signs.

The pre-endoscopy assessment, though important, can only be a guide to the type and degree of pathology discovered at endoscopy. The combination of a thorough history, examination and limited investigation can in some conditions (e.g. mild laryngomalacia) provide sufficient diagnostic probability to avoid initial endoscopy. The type of stridor may be characteristic of a particular pathology but is never diagnostic.² A second pathology may be present in up to 20 percent of cases though few will require treatment.³ The diagnosis can only be confirmed with certainty after endoscopy. This does not mean that every child with stridor requires endoscopy. In most children seen in a secondary or tertiary referral centre, endoscopy will be required and in most conditions is the gold standard. Dynamic conditions such as vocal cord palsy and tracheobronchomalacia often prove difficult to confirm or exclude at routine endoscopy.

CHARACTERISTICS OF STRIDOR

The characteristic sound of stridor even in a common condition such as laryngomalacia⁴ is so variable as to be of little diagnostic use on its own. The site of the abnormal vibration can rarely be tracked down with the aid of a stethoscope, because of the variable transmission of sound through the thorax. However, auscultation is useful to detect heart murmurs and wheeze. Typically, inspiratory stridor is due to an extrathoracic obstruction (Figure 86.1) from the larynx or high trachea. Bronchial or low tracheal obstruction produces an expiratory stridor. Biphasic stridor can occur with obstruction anywhere in the tracheobronchial tree. Even if expiratory stridor is absent, a prolonged expiratory phase may be present indicating an intrathoracic obstruction (Figure 86.2). Laryngomalacia is said to have a 'musical quality', vocal cord palsy a 'breathy quality'. The cough in tracheomalacia is said to be 'barking'.

ASSOCIATED FEATURES

Subcostal, intercostal and suprasternal recession may occur separately or together and also be associated with

Figure 86.1 Showing collapse and increasing obstruction on inspiration with extra-thoracic obstruction.

Figure 86.2 Showing collapse and increasing obstruction on expiration with intra-thoracic obstruction.

'see-saw' respiration. The severity of recession is a better indicator of the severity of airway compromise than the degree of stridor. The severity of stridor can paradoxically become less as obstruction worsens due to the diminishing airflow. No comfort should be taken from the fact that a child still looks pink. Cyanosis is a late event and suggests obstruction has been severe or prolonged.

If a supralaryngeal component is suspected, nasal patency should be assessed with a mirror, a wisp of cotton wool or using the bell end of a stethoscope. Make a conscious assessment of jaw and tongue size.

Both stridor and recession will vary as the child rests, cries and sleeps but it is rare to be able to demonstrate a similar repeatable change with position. Observing the child feeding is extremely valuable, particularly if there is poor feeding or aspiration.

Examine the ears, nose, throat and lastly neck with the usual caution that you must not use any instrumentation to examine the throat of child in whom epiglottitis is suspected.

Pre-endoscopy investigations

Investigations need to be carefully selected on the basis of the history and examination.

BLOOD GAS ANALYSIS

In acute airway obstruction, transcutaneous O₂ saturation monitoring is extremely helpful. It is noninvasive (unlike arterial blood gases) and yet much more sensitive than clinical estimation. However, considerable airway obstruction can occur without desaturation so long as the child continues to have the energy to overcome the obstruction. CO₂ build-up and respiratory acidosis can develop without desaturation especially if O₂ is being administered. Hypoxaemia occurs with tiredness more often than progression of the underlying obstruction. Transcutaneous CO₂ measurement is unreliable particularly in the shocked patient so there is still a place for arterial blood gases.

IMAGING

The value of radiological investigations has been reviewed retrospectively by Tostevin *et al.*⁵ A plain chest x-ray and a lateral view of the neck, digitally enhanced to demonstrate the subglottis, oropharynx and nasopharynx, may be all the radiology required. A plain chest x-ray may show the ground glass appearance of bronchopulmonary dysplasia or mediastinal shift with obstructive emphysema of a foreign body but it does not demonstrate the major airways well. If a foreign body is suspected in young children, diaphragmatic screening with videofluoroscopy is a more sensitive technique. In older children, inspiratory and expiratory films may demonstrate diaphragmatic immobility on the side of the obstruction.

Videofluoroscopy is also an excellent way of demonstrating tracheomalacia. It can be combined with a contrast swallow looking for vascular compression^{6,7} and aspiration.

Bronchography is enjoying something of a renaissance after the introduction of safer nonionic contrast media. It is particularly useful for the lower airway demonstrating tracheobronchial stenosis and malacia. Opening pressures of the collapsed bronchi and lower trachea can be measured and used to determine the level of airway support needed.

Computerized tomography (CT) and magnetic resonance imaging (MRI)^{8,9,10} are not usually sufficiently sensitive to fully characterize a stenotic segment, which can be more accurately assessed at endoscopy. If available, helical CT with multiplanar reconstruction may offer better definition of tracheal lesions.^{11,12} MRI and CT can, however, both demonstrate extrinsic compression, particularly abnormal vasculature.

Echocardiography can be used to screen for vascular compression, demonstrating most but not all abnormal

vasculature as well as coincidental or symptomatic congenital heart disease.

With experience, ultrasound of the vocal cords can be used to demonstrate vocal cord palsy with reasonable accuracy to complement the endoscopic findings.

ASSESSMENT OF REFLUX

Gastro-oesophageal reflux^{13,14,15,16} can be assessed with a contrast study, milk scan, pH probe study or lower oesophageal biopsy. Contrast studies have low specificity and sensitivity and are very dependent on the radiologist for appropriate positioning and interpretation. The other investigations are more sensitive but are usually interpreted by gastroenterologists looking for reflux into the lower oesophagus. The laryngologist is interested in the pH in the upper oesophagus and pharynx, which can be measured using a second probe in the upper oesophagus. Double probe pH studies are at present more a research tool because of technical difficulties with the probe and little in the way of normative data. Many episodes of reflux occur without acid or at least any drop in pH; the significance of these non-acid reflux events for the larynx remains to be seen.

Even if reflux is demonstrated by any of the above means, it is difficult to decide if the reflux is secondary to the airway obstruction with a negative intrathoracic pressure drawing gastric contents into the oesophagus or if the reflux is a separate finding. Occasionally the reflux may be the primary factor with secondary reflux laryngitis. Reflux is considered in detail in Chapter 100, Gastro-oesophageal reflux and aspiration.

RESPIRATORY FUNCTION TESTS

Airway obstruction that worsens during sleep is usually a feature of pharyngeal obstruction such as adenotonsillar obstruction or a craniofacial anomaly. Laryngomalacia¹⁷ and indeed almost any laryngotracheal pathology are rarely worse during sleep. A sleep study is not often used in the assessment of the stridulous child.

Lung function tests such as flow-volume-loops will help localize the site of obstruction but require a degree of patient cooperation. Other lung function tests such as peak flows or more ventilation/perfusion scans are selected with the advice of a pulmonologist.

In summary, a careful history, examination and carefully chosen investigations may suggest a diagnosis but only endoscopy will confirm the diagnosis.

Endoscopy

The two objectives in paediatric airway endoscopy are safety and accuracy. To achieve these objectives requires not only a full range of specialized paediatric endoscopy equipment (Table 86.5) but, most significantly, a high

Table 86.5 British Association for Paediatric Otorhinolaryngology minimum equipment standards for paediatric airway endoscopy.

Equipment
An adjustable laryngeal suspension system
An operating microscope with 400f lens
A selection of age-appropriate paediatric laryngoscopes of varying size and with a variety of viewing angles to include a retrospective telescope
Dedicated laryngeal microsurgical instruments, e.g. microscissors, probes, cupped and straight forceps
A selection of age-appropriate ventilating bronchoscopes with Hopkins rod telescopes to fit
A suitable light source with fiberoptic cables
A camera and monitor with image-capture facilities – video and still
A colour printer
A selection of forceps for the removal of foreign bodies
Optical forceps with rigid telescope(s) of appropriate length
A selection of fiberoptic bronchoscopes and a nasopharyngoscope
A full range of paediatric tracheotomy tubes
Cabinets and storage facilities for the above

level of experience in the endoscopist, anaesthesiologist and nursing staff. A systematic approach will provide a diagnosis in most cases.¹⁸

FLEXIBLE ENDOSCOPY IN THE OFFICE OR WARD

The introduction of ultra-thin endoscopes^{19, 20, 21} with good optics and a diameter of less than 2 mm has allowed even neonates to be endoscoped without the need for a general anaesthetic. Per-oral passage of an endoscope using a finger between the child's gums to protect the instrument is preferred by many to transnasal introduction. This is usually considered a screening procedure. The view, particularly of the larynx, is often suboptimal. No invasive diagnostic or therapeutic procedure can be undertaken and even if an abnormality is demonstrated (such as laryngomalacia) a second pathology can easily be missed. Ward flexible endoscopy without anaesthesia is particularly useful to assess dynamic abnormalities such as vocal cord palsy prior to a formal endoscopy in the operating room. Flexible endoscopy under sedation in an endoscopy suite is widely practised by paediatricians and pulmonologists^{22, 23, 24} and is becoming more popular with otolaryngologists as an adjunct to rigid endoscopy.²⁵

LARYNGOTRACHEOBRONCHOSCOPY

Laryngotracheobronchoscopy (LTB)^{26, 27} (Figures 86.3 and 86.4) using rigid Hopkins rod telescopes is the gold standard in the assessment of the stridulous child. It is now a highly technical procedure. The whole team (surgeon, anaesthetist and nursing assistant) need to work closely together to perform the examination safely, and to optimize the assessment.

The advent of video and high quality image reproduction on a viewing monitor has been invaluable in training.

Assessment is now safer as the anaesthetist can now see the image on screen and the team can be ready with equipment for the next stage.

If the examination is for assessment, it is vital that accurate records are kept to allow comparison with future examinations. This is facilitated by using a standardized data capture form within a department.²⁸ Use of a recognized staging system is important for publication of results. Prints from the video form a valid record for static conditions whilst for dynamic conditions a videotape is unparalleled. The latest digital image recording systems allow multiple rapid images to be stored during the procedure with only a selected few being printed or converted to slide format. As computer memory becomes even more affordable, digital video recordings as well as still images can be saved and archived. This provides an invaluable source of information for sequential clinical comparisons, medicolegal purposes and teaching.

ANAESTHESIA FOR AIRWAY ENDOSCOPY

Major units from around the world use different techniques and it is probably more important that a team of surgeon, anaesthetist and nurse work together than that one particular technique is followed. Practice varies between centres as to whether intubation is used at the start of the procedure but most units would now use spontaneous respiration rather than paralysis and jet ventilation.

Induction

Some units will use an atropine premedication to facilitate a dry surgical field and improve the efficacy of topical anaesthesia. To be effective it needs to be given by intra-muscular injection. Preoperative steroids are a good safeguard if significant stenosis is suspected. Intravenous

© Hodder Arnold / Scott-Brown 7E

Figure 86.3 Microlaryngotracheobronchoscopy (MLTB) in progress. The surgeon is using a CO₂ laser.

© Hodder Arnold / Scott-Brown 7E

Figure 86.4 Laryngotracheoscopy in progress.

induction is preferable for older children though gas induction may be needed in infants, those with poor venous access and those with a precarious airway. Topical lignocaine spray to the cords needs to be carefully measured as the preparations used in adults can easily result in overdose.^{29, 30} Intravenous suxamethonium can be given if the patient is stable. It may be given prior to the lignocaine spray to avoid laryngeal spasm as well as to facilitate intubation if required.

Intubation

Once intubated the child can be quickly ventilated down to a level of anaesthesia which allows the passage of endoscopes without gagging but maintains spontaneous respiration. The laryngoscope can be adjusted whilst the child is still intubated. Nasotracheal intubation allows the endotracheal tube to be withdrawn into the nasopharynx once the child is breathing spontaneously.

Nonintubation technique

After induction the child is breathed down to the same level as above which, in the presence of any obstruction, can take some time. The advantage is that the endoscopist

has a view of an airway that has not been altered by the passage of an endotracheal tube. At any time airway control can be regained with intubation or the use of an endoscope.

Jet ventilation

This technique allows the child to be paralysed, preventing any coughing or gagging but gas exchange is maintained with short pulses of injected anaesthetic gas, simulating normal respiration.^{31, 32, 33} The pressures required³⁴ are higher than physiological levels, with a risk in neonates and smaller children of a pneumothorax. Few centres still use this technique as dynamic conditions such as malacia and cord palsy cannot be identified.

Laryngeal mask

This is useful for fibre-optic bronchoscopy, particularly if the patient is difficult to intubate because of mandibular hypoplasia.^{35, 36}

Tracheotomy tube anaesthesia

If use of the laser is considered³⁷ in a child who already has a tracheotomy tube, this should be changed prior to anaesthesia and a metal tube used.

Maintenance of anaesthesia

Halothane and oxygen maintain a level of anaesthesia that allows a thorough examination in a child who is breathing spontaneously. Halothane has the great advantage that it is relatively nonirritant to the airway. Sevoflurane³⁸ is also nonirritant but has the advantage of rapid onset and no pungency, allowing delivery of high concentrations immediately. Experience with this new agent is limited but the advantage of rapid induction may be offset by rapid termination of effect during periods of relative hypoventilation or airway obstruction. The anaesthetist needs to be able to control anaesthesia in response to surgical conditions and for this a video monitor is

invaluable. Peroperative O₂ monitoring is now routine³⁹ and with time CO₂ monitoring is also becoming routine.⁴⁰

MICROLARYNGOTRACHEOSCOPY TECHNIQUE

The following description assumes that the patient has been intubated, a suspension laryngoscope is employed and that the larynx is to be examined with a microscope or a rigid telescope.

A small sandbag is usually required under the shoulders to prevent hyperextension of the neck, with sandbags laterally to support the long thin heads of ex-premature neonates. A Mayo table supports the laryngostat clear of the chest.

It is important to prepare and check all equipment prior to the endoscopy so that the endoscopist is fully prepared for all eventualities. The range of Hopkins rod telescopes should include all lengths and diameters that could be needed and a 30° telescope to assess the supraglottic larynx without splinting. A microscope should be available though is often not used unless surgical intervention is required when two hands are needed for manipulation. If a microscope is used, a 400-mm lens allows the use of standard laryngeal instruments but a 350-mm lens brings the patient closer allowing easier manipulation of larynx, which is particularly important in small neonates. For routine examination, the telescope and camera can be held in the left hand with a probe used in the right. The view and images available are far superior to those via the microscope. Every unit should have a chart listing the appropriate sizes of bronchoscope for different ages. The age-appropriate bronchoscope needs to be checked and one at least a size smaller has to be instantly available as well. Antifog solution is only effective if freshly applied to the telescope lens.

Laryngeal examination is usually begun with the endotracheal tube in place by gently inserting the lubricated suspension laryngoscope, taking care to protect the teeth and lips and to keep the tongue central to provide a well-centred view. As in adults, it is important to check the overall appearance of the supraglottis and laryngopharynx during introduction of the laryngoscope. The endotracheal tube, if present, is followed to the tip of the epiglottis, gently lifting the epiglottis forwards making certain that the epiglottis does not curl up in front of the laryngoscope preventing a complete view of the anterior commissure. An overall assessment of the larynx can be made with the tube still *in situ*, providing a degree of stability that is particularly welcome in the child with a compromised airway.

Laryngeal examination with the endotracheal tube removed provides a superior view and by using a probe to move the arytenoids independently, the mobility of the cricoarytenoid joints can be assessed. If an interarytenoid

scar is present the arytenoids will not move independently. A posterior laryngeal cleft is excluded by passing the probe between the arytenoids, comparing the lower limit of the interarytenoid groove with that of the posterior commissure. Finally, the cords need to be gently moved apart to inspect the subglottis.

The time available for the examination will depend on the airway. In a child breathing spontaneously with a normal airway and normal lung function, anaesthesia can be maintained solely by the use of inhalational agents with the endotracheal tube withdrawn into the pharynx. In others the time may be very limited and it is essential to be prepared to move ahead with bronchoscopy at any stage. If anaesthesia is stable, a sucker can be placed in the laryngeal inlet to mimic laryngomalacia – the ‘Narcy test’. Photographs can be taken at this stage with a wide Storz photographic telescope. If there is significant subglottic stenosis, an ultra fine telescope passed through the laryngoscope will cause less trauma than a bronchoscope.

BRONCHOSCOPY

Traditionally, a ventilating bronchoscope (Figure 86.5) has been used which provides a means of actively ventilating the patient if required. With spontaneous ventilation, a smaller diameter rigid Hopkins rod telescope can be used with less trauma and less splinting of the airway. An age-appropriate bronchoscope is used unless stenosis is suspected. Neonates pose particular problems if manipulation of the airway is required.^{41, 42} An anaesthetic laryngoscope can be used in the vallecula to lift the larynx forward whilst passing the bevel of the bronchoscope through the vocal cords under video control on the monitor. The main bronchi, the carina, the trachea and the subglottis are all systematically examined and videographs or digital images recorded. Tracheomalacia should be observed with a small bronchoscope withdrawn from the area in question and without positive airways pressure to avoid splinting. The

ratio of cartilage to trachealis is significant in recording the type of malacia and in judging if aortopexy is likely to be successful.

DYNAMIC ASSESSMENT OF LARYNX ON RECOVERY FROM ANAESTHESIA

Typically, this can be achieved by withdrawing the bronchoscope to just posterior to the tip of the epiglottis. This affords a good view of the vocal cords to exclude a cord palsy and of the arytenoids to exclude the common posterior form of laryngomalacia, though anterior collapse of the epiglottis may be masked. In this case, a 30° or 70° telescope should be used. The anaesthetist should call the phase of respiration to check for paradoxical vocal cord movements.

An excellent technique for dynamic assessment of the vocal cord movement is to insert a laryngeal mask with a fibre-optic bronchoscope passed through this to just above the laryngeal inlet.⁴³ If a bilateral vocal cord palsy is suspected and structural abnormalities have been excluded with a full microlaryngoscopy and rigid bronchoscopy, it is sometimes necessary to reschedule the patient for a further examination in which a laryngeal mask and fibre-optic scope are used from the outset, reducing the influence of prolonged anaesthesia on the cord function. An alternative is to use a 30° scope which gives a view of the larynx without splinting the supraglottis.

MANAGEMENT OF ACUTE AIRWAY OBSTRUCTION

Medical (in ward or emergency room)

ASSESSMENT

In the acute situation, assessment, history taking and active resuscitation will often proceed in parallel. In the example of a child arriving in the emergency room with suspected LTB, the physician will be assessing the child for the degree of airway obstruction by gauging the recession and dyspnoea at the same time as asking the mother for the length of history and whether there is any possibility of foreign body inhalation. The nurse will be checking the oxygen saturation and setting up humidified oxygen. Another member of the team may have to call and alert the operating room that the child may need intubation as well as calling the anaesthesiologist and otolaryngologist. This situation clearly benefits from careful planning, with most units having a protocol for how to deal with the stridulous airway-compromised child. The protocols vary considerably with some units insisting on the presence of an otolaryngologist^{44, 45} at intubation in case a tracheotomy is needed while others have managed for many years without.

OXYGEN THERAPY

With an obstruction to airflow, but normal alveolar function, raising the concentration of inspired oxygen will reduce the ventilatory requirement to maintain an adequate oxygen saturation in the blood but will do nothing to aid CO₂ excretion. So long as the possibility of chronic hypercarbia is appreciated, oxygen is a useful drug in the treatment of airway obstruction.

HUMIDIFICATION

There is no objective evidence⁴⁶ that raising the humidity of the inspired air is beneficial, though many units still use humidity tents or 'croupettes' that have the disadvantage of decreased visibility as well as doing little to allay the fears of a frightened child.

PHARMACOTHERAPY

Intravenous (and oral) steroids such as dexamethasone have been shown to be beneficial in croup (LTB) with inhaled steroids having a similar effect. Nebulized budesonide⁴⁷ can be used at home for children with recurrent croup and is usually thought to be superior to oral dexamethasone, though one study showed no difference.⁴⁸ Klassen⁴⁹ [****] summarizes the situation, 'All children with croup symptoms who demonstrate increased work of breathing in the clinics or emergency departments should be treated with glucocorticoids'. This treatment may be with nebulized budesonide (2 mg) or oral or intra-muscular dexamethasone (dose may be 0.15–0.6 mg/kg). Oral dexamethasone may be the best option because of its ease of administration, widespread availability, and lower cost. L-Epinephrine (5 mL of 1:1000) or racemic epinephrine (0.5 mL) should be considered for children with croup who have moderate or severe distress.

Surgical management in the operating room

The increasing use of intubation as an alternative to tracheotomy in acute airway obstruction has been brought about partly by technological advances in anaesthesia and partly by the realization that paediatric tracheotomy, even short term, brings with it numerous problems. Even with a skilled anaesthetist and careful monitoring it is possible that unexpected pathology will be encountered making intubation impossible. Severe subglottic stenosis, impacted foreign bodies and advanced epiglottitis are obvious examples but rarer examples occur such as laryngeal aplasia with ventilation being achieved via a tracheo-oesophageal fistula.

It is this uncertainty combined with the precipitate nature of paediatric airway obstruction that makes it

mandatory in most hospitals for an ENT surgeon to be informed if a child with airway obstruction of unknown aetiology is to be intubated. Depending on the circumstances, it may be necessary to have an emergency tracheotomy set open with the correct size tube already selected.

Once the child has been gassed down slowly it is possible to inspect the larynx and exclude epiglottitis. This may be all that is required and the child can then be managed on a nasal prong with perhaps some continuous positive airways pressure (CPAP) applied. If intubation is required, it is important to minimize any damage to the already inflamed subglottic mucosa by very gentle intubation with a small soft tube just large enough for adequate ventilation and suction of secretions. Even if the initial intubation is oral, which tends to be easier, the tube should be replaced with a nasal tube which is more secure. At this stage, the fit of the tube can be assessed by checking for a leak and the tracheobronchial secretions sucked clear. If the secretions are very tenacious or there is still an element of airway obstruction, a ventilating bronchoscope should be passed to exclude bacterial tracheitis^{50, 51, 52, 53} or a foreign body. In other clinical circumstances the benefit from endoscopy of having seen the degree of pathology is usually outweighed by the trauma that occurs, particularly with the passage of a bronchoscope as opposed to the smaller diameter of a fine telescope.

Significant tracheobronchomalacia is another reason for continuing airway difficulty after intubation and this will usually respond to CPAP.

Emergency tracheotomy

With experienced paediatric anaesthetists this is now unusual.^{44, 45} Otolaryngologists are often asked to attend a potentially difficult intubation, but are rarely needed. A ventilating bronchoscope may be easier to pass than an endotracheal tube and an endotracheal tube mounted on a Hopkins rod telescope may be useful in a difficult intubation (Figure 86.6). It is easy to become complacent but, if emergency tracheotomy is required, the

surgical set and appropriate tube need to be instantly available. It is important to stay strictly in the midline so the child needs to be carefully positioned without neck or head deviation. A finger either side of the larynx is helpful with a vertical incision through skin and down to the trachea. If a paediatric tracheostomy tube is not available, a paediatric endotracheal tube can be used, ensuring it remains above the carina.

KEY POINTS

- Stridor is the noise from a narrowed airway. The aim of the history, examination and special examinations is to determine not only the site and cause of the obstruction (the diagnosis) but also its effect on the airway (the severity).
- Hypoxaemia is a late feature of progressive airway obstruction, particularly in children treated with oxygen.
- In the acute situation, assessment, history taking and active resuscitation will often proceed in parallel.
- Laryngotracheobronchoscopy is the gold standard in the assessment of the stridulous child.
- Laryngotracheobronchoscopy is now a highly skilled procedure involving a team approach between anaesthetist, endoscopist and operating room personnel. Adequate facilities are not available in all institutions.
- An excellent technique for dynamic assessment of the vocal cord movement is to insert a laryngeal mask with a fibre-optic bronchoscope passed through this to just above the laryngeal inlet.
- Wherever possible, endotracheal intubation is preferable to emergency tracheotomy.

© Hodder Arnold / Scott-Brown 7E

Figure 86.6 A Hopkins rod telescope with an endotracheal tube mounted and ready to introduce in a difficult intubation.

Best clinical practice

- ✓ Improvement in stridor may paradoxically be due to worsening obstruction. [Grade C]
- ✓ Laryngomalacia is common but it is important not to assign failure to thrive to this without first having considered and excluded other causes. [Grade B]
- ✓ Rapid progression of airway obstruction typically occurs in acute infection and in foreign body inhalation. [Grade C]
- ✓ In suspected epiglottitis, instrumentation of the oral cavity and pharynx for clinical examination must be avoided. [Grade D]

- ✓ All children with croup who demonstrate increased work of breathing should be treated with glucocorticoids. [Grade A]
- ✓ If a child with airway obstruction of unknown aetiology is to be intubated, an ENT surgeon should be informed. It may be necessary to have an emergency tracheotomy set open with the correct size tube already selected. [Grade D]
- ✓ A difficult endotracheal intubation may be facilitated by the use of a small ventilating bronchoscope or by passing a Hopkins rod telescope on which a narrow endotracheal tube has been mounted. [Grade D]

Deficiencies in current knowledge and areas for future research

- A growing trend toward specialization within otolaryngology will ensure that airway endoscopy in children is increasingly the remit of otolaryngologists with a special interest and training in this work.
- Improved optics, image capture facilities and anaesthesia will contribute to this.

SEARCH STRATEGY

The opinions in this chapter are supported by a search of Medline and EMBASE using the key words croup, acute laryngotracheitis, acute laryngotracheobronchitis, acute epiglottitis and child. The Controlled Trials Register of the Cochrane Library was also searched. The search was initially restricted to randomized controlled trials and metaanalyses and then widened, focussing on diagnosis, management and immunization.

INTRODUCTION

Laryngeal infection in childhood causes airway obstruction, of which the cardinal symptom is stridor. In the developed world, 'croup' – a clinical scenario characterized by a combination of stridor hoarseness and a typical barking cough – is the commonest (90 percent) cause of acute airway obstruction in children. Epiglottitis has been the next most common infective cause but is now seen much less frequently due to the widespread introduction of *Haemophilus influenzae* b (Hib) vaccine; bacterial laryngotracheobronchitis and diphtheria are less common. The differential diagnosis of acute acquired stridor includes 'spasmodic croup', retropharyngeal abscess, angioneurotic oedema, neoplasia, acute laryngeal trauma and foreign body aspiration. 'Spasmodic croup' is included in this chapter because of the similarity of the

clinical picture to croup. Aetiology is uncertain but it is not thought to be due to acute laryngeal infection.

In this chapter the various clinical syndromes of acute laryngeal infection are discussed and their distinctive features emphasized. For a number of these conditions several terms have evolved over the years; these are included in the headings for ease of reference but the first term, that most commonly used in the UK, is used in the text. The effects of immunization programmes on the changing patterns of disease are examined. The efficacy of medical treatment and the role of endotracheal intubation and/or tracheostomy for safe airway management in the different conditions are considered.

Good management depends on teamwork involving the primary care physician, the paediatrician, the paediatric otolaryngologist, the paediatric anaesthetist and the paediatric intensive care physician. Multidisciplinary

evidence-based protocols should be established and followed to optimize outcomes.

CROUP (ACUTE LARYNGOTRACHEOBRONCHITIS, VIRAL LARYNGOTRACHEOBRONCHITIS)

Croup typically presents as a clinical syndrome of hoarseness, inspiratory or biphasic stridor and barking cough, due to mucosal oedema of the larynx and trachea. There is usually a preceding history of upper respiratory tract symptoms with fever and malaise. It is classically caused by *parainfluenza virus type I*. It can be caused by other viruses including *parainfluenza virus type II*, respiratory syncytial virus (RSV) and *influenza virus types A and B*, and can also complicate measles. It usually affects children between six months and three years of age with a peak incidence in two year olds. Boys are more commonly affected than girls. There is a seasonal variation; in the USA a minor peak in hospital admissions for croup has been noted in February and a major peak in October in odd numbered years, coinciding with biennial epidemics of *human parainfluenza type I* infection. The annual incidence of croup in children younger than six years ranges from 1.5 to 6 percent. [**]

Croup is usually self-limiting; 50 percent of children improve within 24 hours of the onset of symptoms, and most recover within four days without treatment. However, airway symptoms can become serious and even life-threatening. In the absence of medical therapy, 20 percent of patients may be admitted to hospital and 10 percent of these may require intervention for acute airway obstruction, either intubation or tracheostomy depending on local services. Coexisting bronchopneumonia or measles infection are indicators of poor prognosis. The diagnosis is a clinical one, but in those severe cases which reach hospital, if there is a diagnostic dilemma, a radiograph of the thoracic inlet will show characteristic narrowing of the subglottis on an anteroposterior view ('steeple' or 'pencil tip' sign) (Figure 87.1). [**]

There are inflammatory changes throughout the airway in croup but the critical symptom of stridor is due to oedema in the subglottis, the narrowest part of the paediatric airway. Just 1 mm of oedema in an 18-month old child with a subglottic diameter of 6.5 mm will reduce the cross-sectional area by approximately 50 percent. Laminar airflow (proportional to the fourth power of the radius – 'Poiseuille's law') is thus greatly reduced. Some children are more at risk of severe symptoms than others; factors predisposing to severe symptoms include pre-existing subglottic or tracheal narrowing, chronic lung disease and airway reactivity, characterized by a history of inhalant or food allergies. The Westley Croup Score (Table 87.1) allows the severity of symptoms to be classified and allows comparisons of severity to be made.¹ It has been clinically and radiologically validated, the total

Figure 87.1 'Steeple' or 'pencil tip' sign. Narrowing of the subglottic airway owing to mucosal oedema in croup (arrows). Figure courtesy of Ben Hartley.

score correlating with the diameter of the tracheal lumen. A maximum score is 17, a score of 2–3 equates to mild croup, 4–7 to moderate croup and 8 or more to severe croup. [***]

For mild croup, treatment can be supportive, with reassurance of both carers and child, and observation and monitoring of the child's symptoms, but without separating the child from its carer(s) as this will increase anxiety. Sedation is not advised because of the risk of respiratory depression, although chloral hydrate 30 mg/kg has been advocated if sedation seems necessary. Traditionally, it has been recommended that children with croup should be nursed in a humidified environment or mist tent; there is no evidence that this is of clinical benefit although it may be soothing. Nebulized epinephrine (1 mL of 1 in 1000 epinephrine diluted in 3 mL of 0.9 percent saline) has an established role in the acute paediatric airway in reducing mucosal oedema by an alpha-agonist effect causing vasoconstriction and bronchodilation; a maximum effect is achieved within 30–60 minutes, however there is no lasting benefit beyond two hours.¹ It does not alter the natural history of the disease but it may postpone or eliminate the need for an artificial airway, or give symptomatic relief until effective treatment can be given.² It can be administered at the same time as glucocorticoids. [***]

Corticosteroids

The role of corticosteroids in the management of croup is now well established. Corticosteroids have a systemic antiinflammatory effect. There is a reduction in capillary

Table 87.1 Croup score based on Westley system.

Score	0	1	2	3	4	5
Inspiratory stridor	None	Audible with a stethoscope	Audible without a stethoscope			
Retraction	None	Mild	Moderate	Severe		
Air entry	Normal	Decreased	Severely decreased			
Cyanosis	None				With agitation	At rest
Conscious level	Normal					Altered

endothelial permeability and therefore in mucosal oedema, and stabilization of lysosomal membranes, decreasing the inflammatory reaction. Topical corticosteroids theoretically have the added benefit of causing local alpha-mediated vasoconstriction. A number of studies have looked at clinical improvement after corticosteroid therapy. Clinical benefit can be measured by an improvement in croup score, reduced hospital admission rates, shorter length of stay, lower intubation rates or a reduced need for cointerventions such as the administration of epinephrine nebulizers. A metaanalysis in 1989 of nine placebo - controlled trials showed a trend in favour of corticosteroids but no significant benefits.³ This stimulated more rigorous studies and a more recent metaanalysis of 24 studies has confirmed that steroids are effective in relieving the symptoms of croup as early as six hours after treatment.⁴ [***] Recent evidence suggests that glucocorticoid use should be not be confined to moderate or severe cases but should be extended to children with mild croup.^{5,6} The small numbers of patients in each study and the confounding variables make it difficult to make definitive recommendations regarding the superiority of any glucocorticoid, dose, or route of administration.⁷ In the absence of further evidence, an oral dose of dexamethasone (0.6 mg/kg) is preferred because of its safety and efficacy. In a child who is vomiting, nebulized budesonide (2 mg) may be considered. Although equally efficacious,⁸ intramuscular dexamethasone (0.6 mg/kg) cannot be advocated given the potential for muscle necrosis with that route of administration. The use of glucocorticoids in primary care in the early management of croup symptoms has transformed the management of this disorder; affected children now rarely require active intervention to support the airway. [***]

SPASMODIC CROUP (SPASMODIC LARYNGITIS, PSEUDOCROUP, ACUTE SUBGLOTTIC OEDEMA, SUBGLOTTIC ALLERGIC OEDEMA, LARYNGISMUS STRIDULUS)

Some children appear to be prone to recurrent croup-like symptoms. Episodes may not be preceded by upper respiratory tract symptoms but typically begin suddenly, often at night, and resolve after a few hours. Attacks may

be precipitated by gastro-oesophageal reflux. There is an association with low IgA levels and this condition may present in atopic children who later develop asthma or other allergic conditions.⁹ [**]

The symptoms can be relieved by a single dose of oral dexamethasone in a dose of 0.6 mg/kg in the same way as for viral croup.

It is important to consider congenital or acquired mild subglottic stenosis in the differential diagnosis of infants presenting with 'recurrent croup'. In persistent cases endoscopy is mandatory.¹⁰

BACTERIAL LARYNGOTRACHEOBRONCHITIS (PSEUDOMEMBRANOUS CROUP, BACTERIAL TRACHEITIS, MEMBRANOUS LARYNGOTRACHEOBRONCHITIS, NEONATAL NECROTIZING TRACHEOBRONCHITIS)

This is a severe form of laryngotracheobronchitis associated with sloughing of the respiratory epithelium and profuse mucopurulent secretions. Initial presentation is similar to croup but there is no response to steroids. The child rapidly progresses to a toxic state and there may be respiratory decompensation. Although it typically affects children older (mean age four years) than the usual age group for croup, like croup, it is commoner in boys than girls, and there is no single factor, clinical, radiological or laboratory-based which reliably distinguishes it from croup.¹¹ It is a much less common condition than croup. However, there is increased susceptibility in children with Down syndrome or immunodeficiency. [**]

The diagnosis can only be confirmed on airway endoscopy; there is a pseudomembrane in the subglottis and trachea and thick mucopus and debris extending into the bronchi (Figure 87.2). Direct laryngotracheobronchoscopy under general anaesthesia and removal of all tracheal secretions, with pulmonary toilet, is mandatory. It is then almost invariably necessary to secure the airway by endotracheal intubation for a period of days.¹² The distal airway and the tube itself remain at continued risk of obstruction by secretions and vigilant expert nursing care is essential.

Once the diagnosis is established, broad-spectrum parenteral antibiotics should be commenced immediately. They can later be adjusted in line with the results of

© Hodder Arnold / Scott-Brown 7E

microbiological studies. *Staphylococcus aureus* is the pathogen most commonly isolated from tracheal cultures although *Haemophilus influenzae*, *Moraxella catarrhalis*, *Streptococcus pneumoniae* and *Pseudomonas aeruginosa* have also been reported. Blood cultures are rarely positive. [**]

Complications of this dangerous condition include airway stenosis, respiratory failure, toxic shock syndrome, anoxic encephalopathy and death.

Ventilated newborns with an unstable haemodynamic state are at risk of potentially fatal desloughing of the tracheobronchial mucosa. This may be characterized by repeated episodes of acute airway obstruction. Management involves repeated therapeutic tracheobronchoscopy to free the airways.¹³

DIPHTHERIA

Diphtheria is a rare condition in countries which have a routine childhood immunization programme, but remains an important differential particularly in immigrant populations in the diagnosis of acute laryngeal infection in children. Diphtheria remains a significant public health problem in the developing world. The causative organism is *Corynebacterium diphtheriae*. There are three strains, *gravis*, *intermedius* and *mitis*; it is the *gravis* strain which is responsible for major epidemics and for the high mortality. [****] The early clinical picture of upper respiratory tract symptoms is due to the effects of the organism itself. Delayed effects are due to the release of endotoxin. Diphtheria is a disease particularly affecting young children; it is rare over the age of ten years.

Initial symptoms are of pharyngitis with sore throat and malaise. The child is feverish and on examination there is a typical appearance of the pharyngeal tonsils with necrosis and the development of a characteristic grey pseudomembrane over the surface. This consists of necrotic tissue, bacteria and a rich fibrinous exudate. Early removal causes bleeding but the pseudomembrane may separate more easily later in the course of the disease. There may be a bull-neck appearance due to cellulitis and regional lymphadenopathy.

Laryngeal diphtheria rarely occurs without prior pharyngeal infection. After progressive dysphagia and toxæmia, inspiratory stridor and a barking cough develop; the cough is frequently paroxysmal and exhausting. Death may follow owing to acute airway obstruction or as a result of the later effects of the endotoxin.

The endotoxin can cause a toxic myocarditis in the second week of the disease and this may be fatal. Peripheral neuritis may also occur, palatal paralysis being the most common effect of peripheral neuropathy and presenting with nasal regurgitation of food and hypernasal speech.

Successful treatment depends on early diagnosis, and the administration of high dose benzylpenicillin and antitoxin (10,000 to 100,000 units depending on the severity of infection). Airway management consists of removal of the laryngeal membrane, administration of oxygen and humidification, and endotracheal intubation or tracheostomy if necessary. Systemic steroids may reduce the need for airway intervention.¹⁴ Bed rest is recommended until the danger of myocarditis is past.

ACUTE EPIGLOTTITIS (SUPRAGLOTTITIS)

The classical presentation of acute epiglottitis is well described. It is of a toxic child with a short history of sore throat, inspiratory stridor, muffled voice and drooling due to odynophagia and dysphagia. Left untreated there is progressive respiratory distress. The child is febrile, tachypnoeic and traditionally will be sitting upright, with the neck extended to optimize the airway, and using the arms to provide support to the shoulder girdle to maximize the efficiency of the accessory muscles of respiration. It is commonest between the ages of three and six and there is an increased prevalence in winter and spring. [**/*]

When acute epiglottitis is suspected, pharyngeal examination should not be attempted, as simple manipulation with a tongue depressor may precipitate acute airway obstruction, although the use of a fiberoptic or small rigid endoscope can assist the diagnosis in patients with an atypical presentation.¹⁵ Direct examination of the airway should not be delayed, but should be undertaken in a controlled setting such as an operating room or paediatric intensive care unit by personnel skilled in airway intervention; endoscopic evaluation will confirm gross erythema and oedema of the supraglottic structures

(Figure 87.3). When the diagnosis is confirmed, the airway should be secured by endotracheal intubation. If this is unsuccessful, a rigid bronchoscope may be passed to allow tracheostomy. Endotracheal intubation is usually required for safe airway management. [*/*] Despite this, mortality remains as high as 2 percent.¹⁶

Investigations prior to securing the airway are contraindicated but a soft tissue lateral radiograph of the neck will typically show a thickened oedematous epiglottis – the ‘thumb sign’ (Figure 87.4). The causative organism can be identified from nasopharyngeal swabs, laryngeal swabs, sputum samples or blood cultures taken after intubation. Traditionally, acute epiglottitis has been a manifestation of invasive Hib infection. This can be confirmed as the cause in partially treated patients by Hib antigen detection in concentrated urine specimens. Other organisms are less common causes of acute epiglottitis; they include *meningococcus*, *Haemophilus parainfluenzae* and *Staphylococcus aureus*. Immunocompromised individuals are at increased risk of epiglottitis. It may then be due to atypical organisms such as *Streptococcus pneumoniae* or *Candida albicans*. Children with acute epiglottitis should be screened after recovery from the acute episode to ensure there is no underlying predisposing condition. Group A beta-haemolytic *Streptococcus* is a recognized cause of acute epiglottitis in older children and adults. [**]

Treatment is with intravenous antibiotics; ampicillin resistance due to beta-lactamase production is now over 50 percent in *Haemophilus influenzae*, so empirical treatment with third-generation cephalosporins for five to seven days is advised. Chloramphenicol is an alternative in the event of allergy to cephalosporins. Penicillin-sensitive *Streptococci* are the usual cause of acute epiglottitis in children who have been immunized against Hib and they should be treated accordingly.

Figure 87.3 Acute epiglottitis. Endoscopic appearance. Reproduced by permission of Bruce Benjamin.

Recovery is characterized by resolution of systemic symptoms and the supraglottic inflammation. The child can then be extubated and discharged from hospital. Since the introduction of Hib immunization, Rifampicin prophylaxis has been recommended to eradicate the carrier state for unimmunized members of the household who are four years old and younger and unimmunized day care contacts aged two or younger. [*/*]

Despite the declining incidence of this disease and the changing bacteriology, there has been no change in its clinical presentation over time. It is critically important that reduced clinical experience is not accompanied by a sharp rise in mortality for affected children.

Haemophilus influenzae type b immunization

In addition to acute epiglottitis, other manifestations of invasive *Haemophilus influenzae* infection include meningitis, septic arthritis, septicaemia, pneumonia and osteomyelitis. Hib has caused more than 90 percent of invasive *Haemophilus influenzae* infection in developed countries. It has been estimated that, prior to the introduction of immunization, Hib caused 41/100,000 infections in newborn to four-year-old children of which more than 50 percent were meningitis,¹⁷ epiglottitis being the next most common presentation (15/100,000).¹⁶ [**]

Routine infant immunization with conjugate Hib vaccine in the UK began in October 1992. Immunization

Figure 87.4 Acute epiglottitis. Radiological appearance of the oedematous epiglottis (arrowed).

is achieved by three primary doses followed by a late booster. The incidence of invasive Hib infections in children under five fell dramatically from an incidence of 23.8/100,000 for the year preceding vaccine implementation to 0.66/100,000 in 1998.¹⁸ A reduction in the incidence of acute epiglottitis of approximately 90 percent has been documented in countries in which an immunization programme has been established. Vaccine failure does occur but in fewer than 10 percent of cases is there an identifiable clinical risk factor predisposing to infection. A small number of cases may be due to infection with an organism other than *Haemophilus* and continued vigilance among clinicians is required.¹⁹ There is evidence that a longer duration of breast-feeding (more than 13 weeks) is associated with a significantly enhanced antibody response to Hib in children aged between 18 months and six years.²⁰ In the Hib vaccine era, non-type b invasive *Haemophilus influenzae* disease has become more common than type b. It is likely to occur in younger children than is the norm for type b infection (16 versus 22 months), but is less likely to be meningitis or epiglottitis and more likely to be pneumonia or bacteraemia.²¹ [**]

AIRWAY MANAGEMENT

For the child presenting with acute airway obstruction due to laryngeal infection, active intervention to secure the airway may be necessary if symptoms are severe. The options to provide an artificial airway include endotracheal intubation and tracheostomy. Prior to 1975, tracheostomy was the standard intervention, then endotracheal intubation was shown to be a safe alternative for acute epiglottitis and subsequently for croup. Endotracheal intubation is now considered preferable to tracheostomy if circumstances permit. However, the choice of intervention may be influenced by the availability of medical and nursing expertise and local hospital services. The intubated child will require specialized intensive care facilities for management whereas the child with a tracheostomy, whilst still requiring nursing expertise for optimal management, can be nursed on a normal paediatric ward.

A team approach to management is essential for optimal outcome. The paediatrician, paediatric anaesthetist, paediatric intensivist and paediatric otolaryngologist must collaborate to develop multidisciplinary evidence-based protocols which take into account the availability of local services. Immunization programmes and advances in medical management are changing patterns of disease and have resulted in a decline in the prevalence of acute airway obstruction due to acute epiglottitis, croup and diphtheria; clinicians with little experience of children with these conditions will depend on protocols for safe practice. If endotracheal intubation is to be undertaken, it should be performed in an operating room or paediatric intensive care unit with personnel and equipment

available and ready to undertake tracheostomy if the airway cannot be secured.

Once an artificial airway is in place, humidified air should be administered to discourage the development of tenacious secretions. The tube should be aspirated regularly, using suction, to prevent tube obstruction. Nursing vigilance to prevent accidental displacement or self-extubation is essential. In ideal conditions, mortality rates can be as low as 1 percent for either intervention.²²

Nasotracheal intubation

Endotracheal intubation for airway obstruction due to acute laryngeal infection is now widely practised with great expertise. When a prolonged period of intubation is anticipated, the nasotracheal rather than the orotracheal route is preferred; nasotracheal intubation is better tolerated so the child requires less sedation, the tube can be secured more reliably and nursing care is easier. The tube is positioned with the patient anaesthetized and the child is then nursed under sedation, fed via a nasogastric tube. The cough and voice are absent during the period of intubation but, after extubation there are normally no sequelae. Complications can occur however and include epistaxis at the time of intubation, the development of sinus sepsis during the period of intubation and hoarseness after extubation. The risk of acquired subglottic stenosis is small but is associated with younger age of the child, larger tube size, serial intubation and longer duration of intubation. It is more common in Down syndrome in which there may be an element of congenital subglottic stenosis as a predisposing factor. A tube one size smaller than that usually considered age appropriate should be used.²³ [**/*]

Extubation can be considered when the child is systemically well, with minimal tracheal secretions. The 'leak test' (air escape around the nasotracheal tube on application of positive pressure ventilation) is helpful but not an absolute prognostic indicator for successful extubation. In acute epiglottitis, visualization of the epiglottis with a flexible nasendoscope can be useful in monitoring resolution of inflammation. Likewise in laryngotracheobronchitis, whether viral or bacterial, the airway can be monitored using flexible endoscopy until a reduction in tracheal inflammation shows that it is safe to extubate. Systemic steroids administered six hours prior to removal of the tube will minimize post-intubation oedema and nebulized epinephrine can assist with airway patency after extubation.

For acute epiglottitis the period of intubation is usually less than 48 hours but for croup and bacterial laryngotracheobronchitis it may be up to a week.²⁴ If extubation fails after the acute laryngeal infection has resolved, and despite all the above measures being taken, this may be due to a pre-existing or developing subglottic stenosis. This, if acute and due to mucosal oedema and ulceration,

may be successfully treated by a cricoid split (see Chapter 89, Laryngeal stenosis). If not however, tracheostomy may become necessary and possibly later laryngotracheal reconstruction.

Tracheostomy

Tracheostomy is not now considered the first choice to secure the airway in acute laryngeal infection. It may be chosen, however, if the availability of nursing expertise and intensive care facilities is limited such that nasotracheal intubation is contraindicated. It may also be necessary if there is severe acute subglottic narrowing precluding the passage of a nasotracheal tube of adequate size for ventilation, or if there has been significant intubation trauma.²⁵ Equipment and personnel to perform an emergency tracheostomy should always be available in case attempted intubation fails.

In one series of 30 patients the median period for which a tracheostomy was required in croup was 11 days.²⁴ However, the largest recent published series of paediatric tracheostomy for croup is from the Red Cross War Memorial Children's Hospital in Cape Town. In that series, 75 percent of children were decannulated within ten weeks of formation of the tracheostomy but 54 percent of children required one or more further procedures after tracheostomy to deal with granulation tissue, suprastomal collapse or subglottic stenosis prior to successful decannulation.²⁶ Clearly nasotracheal intubation is preferable if it is possible and practical depending on local circumstances.

KEY POINTS

- The laryngeal airway in children is narrow, especially in the cricoid region. The mucosa is lax and a comparatively minor swelling may cause significant airway compromise.
- Immunization programmes and improvements in medical management have reduced the prevalence of acute laryngeal infection, and its severity.
- Systemic steroids have transformed the primary care management of croup. Fewer cases now need hospital admission but vigilance is still required.
- Multidisciplinary evidence-based protocols influenced by the availability of local expertise and services should be formulated and followed to optimize outcomes.
- In acute laryngeal infections, nasotracheal intubation is preferable to tracheostomy if it is possible and practical depending on local circumstances.

Best clinical practice

- ✓ Pharyngeal examination is contraindicated if acute epiglottitis is suspected; it may precipitate acute airway obstruction. [Grade D]
- ✓ Children with croup, whether presenting with mild, moderate or severe symptoms, should be treated with oral dexamethasone 0.6 mg/kg at the time of diagnosis. [Grade A]
- ✓ Nebulized epinephrine (1 mL of 1 in 1000 epinephrine diluted in 3 mL of 0.9 percent saline) has an established role in the acute paediatric airway. [Grade B]
- ✓ Subglottic stenosis should be remembered in the differential diagnosis of infants presenting with 'recurrent croup'. Consider endoscopy. [Grade D]
- ✓ Equipment and personnel to perform tracheostomy should be immediately available in case attempted intubation is unsuccessful. [Grade D]

Deficiencies in current knowledge and areas for future research

- Diphtheria remains an important cause of acute airway obstruction in children, especially in immigrant populations and in countries without an active immunization programme.
- As Hib vaccination programmes are extended, the incidence of acute epiglottitis should fall even further.
- The cause of spasmodic croup is still unknown. It may be related to gastro-oesophageal reflux or upper respiratory allergies.

SEARCH STRATEGY

The data in this chapter are supported by a PubMed search using the key words congenital, anomalies, larynx, trachea, bronchi and focussing on diagnosis and treatment.

INTRODUCTION

The exact incidence of congenital abnormalities of the airway is uncertain, but a figure has been quoted for congenital laryngeal anomalies of between 1:10,000 and 1:50,000 births.¹ Some of these children will have more than one anomaly in the airway.² [**]

LARYNX

The larynx is divided into three regions: supraglottis, glottis and subglottis. The supraglottic larynx comprises the epiglottis, aryepiglottic folds, false cords and ventricles. The glottis consists of the vocal cords (also referred to as vocal folds). The subglottis extends from the undersurface of the vocal cords to the inferior border of the cricoid cartilage.

Supraglottis

LARYNGOMALACIA

Laryngomalacia is characterized by partial or complete collapse of the supraglottic structures on inspiration. It is

the most common congenital cause of stridor, but its pathophysiology remains somewhat obscure. The characteristic anatomical abnormalities are undoubtedly primarily responsible for the airway obstruction that occurs on inspiration: the epiglottis is rather long and curled (omega-shaped); the aryepiglottic folds are tall and bulky, while at the same time being short anteroposteriorly and tightly tethered to the epiglottis. The result is a tall, narrow supraglottis with a deep interarytenoid cleft (Figure 88.1). The epiglottis is soft and may curl and collapse. The redundant mucosa and submucosa of the aryepiglottic folds may prolapse anteromedially into the airway. It has been suggested that there may also be an element of neuromuscular immaturity and consequent incoordination of arytenoid movements.

The rather characteristic high-pitched, fluttering inspiratory stridor is usually present at, or shortly after, birth. It is very variable, typically being most noticeable when the infant is active or upset, and may disappear when the child is asleep. The severity of the stridor tends to increase as the child becomes more active during the first nine months of life, and then gradually diminishes until by the age of two years it has generally disappeared. Very rarely, stridor may persist into late childhood.

The diagnosis can be confirmed in the outpatient clinic by flexible fiberoptic laryngoscopy. The neonate is wrapped in a blanket and held firmly in an upright position by a nurse: the endoscope is best passed through the mouth rather than the nose, with the operator's finger inserted between the gums to prevent damage to the fiberoptic bundle. The supraglottic collapse on inspiration, which is typical of laryngomalacia, is easily seen but may obscure the vocal cords, and the examination certainly provides no view below the glottis; a second, coexisting airway pathology therefore cannot be excluded. For this reason a microlaryngoscopy and bronchoscopy under general anaesthesia is necessary if the stridor is severe, if there is failure to thrive or there are any atypical features (it is, of course, also necessary if an adequate view cannot be obtained with the fibrescope); almost 20 percent of such cases will have another airway abnormality, and in nearly 5 percent this will be clinically significant.³ It is important to appreciate that the diagnosis can only be made with the child breathing spontaneously under a very light level of anaesthesia, with the beak of the laryngoscope in the vallecula; the supraglottic collapse is not seen under deep anaesthesia, and will be prevented if the tip of the laryngoscope is introduced into the laryngeal vestibule. Optimum conditions are best achieved at the end of the endoscopy during recovery from anaesthesia.

In approximately 90 percent of reported cases the condition is mild, no intervention is needed and the parents can be reassured accordingly.⁴ In severe laryngomalacia, however, there is serious respiratory obstruction with substantial sternal and intercostal recession; also feeding difficulties which may be compounded by reflux enhanced by the high negative intrathoracic pressures generated, and consequent failure to thrive. Matters are made worse if there are other factors increasing the level

of cardiorespiratory embarrassment, such as congenital cyanotic heart disease. Cor pulmonale may ensue and in cases of severe sternal recession a permanent pectus excavatum may develop. Restoration of an adequate airway is necessary and, until recently, this has meant resorting to tracheostomy.

Fortunately, however, such a drastic step can now be avoided by performing an endoscopic aryepiglottoplasty (sometimes termed a supraglottoplasty).⁵ In this procedure, the larynx is visualized under the operating microscope using as large a laryngoscope as possible, with its beak positioned in the vallecula; the Lindholm laryngoscope is ideal for the purpose. Anaesthesia is maintained via a nasotracheal tube, which also serves to protect the interarytenoid mucosa. Using cup forceps and microscissors (or alternatively a CO₂ laser), each aryepiglottic fold is first divided to release it from the edge of the epiglottis, and the redundant mucosa and submucosal tissue are then excised from over the arytenoids, together, if necessary, with part or all of the cuneiform cartilages. In less severe cases it may only be necessary to incise the tight aryepiglottic fold, thus 'puncturing' the supraglottis.⁶ The 'bridge' of mucosa between the arytenoids is carefully preserved to prevent interarytenoid scarring. Bleeding is minimal, and is easily stopped by the application of neurosurgical patties dipped in topical adrenaline (1:1,000). Neither antibiotics nor steroids are routinely given, complications are very rare, and the stridor is usually improved immediately following the surgery. [Grade B] In cases where the stridor and feeding difficulties persist, an underlying hypotonic neurological disorder is likely.⁷ [**/*]

SACCULAR CYSTS AND LARYNGOCOELES

Congenital saccular cyst is an unusual lesion which may present with respiratory obstruction in infants and young children (Figure 88.2). Similar to a laryngocoele it represents an abnormal dilatation or herniation of the saccule of the ventricle of the larynx; however, it differs from a laryngocoele in that there is no opening into the larynx and it is filled with mucus instead of air. It is considered to form as the result of a developmental failure to maintain patency of the orifice between the saccule and the ventricle, and may be of anterior or lateral type. The anterior saccular cyst extends medially and posteriorly from the saccule and so protrudes into the laryngeal airway between the true and false vocal cords. The lateral saccular cyst is most common in infants and expands posterosuperiorly into the false cord and aryepiglottic fold.⁸

A laryngocoele is classified as internal if it is contained entirely within the laryngeal framework, external if it pierces the thyrohyoid membrane, and combined if there are both internal and external components. It is an uncommon lesion which usually occurs in middle age but may rarely be seen in infancy, when it can produce

© Hodder Arnold / Scott-Brown 7E

Figure 88.2 Right saccular cyst.

respiratory distress which typically becomes worse on crying due to increased distension of the laryngocoele with air. However, a laryngocoele may obstruct and fill with mucus or become infected (laryngopyocoele), thus becoming indistinguishable from a saccular cyst.

Diagnosis is confirmed by endoscopy, except in an external laryngocoele where no abnormality may be seen except on imaging. Saccular cysts are best treated at the initial endoscopy by wide endoscopic marsupialization. [Grade C] If the cyst recurs, then the procedure of choice is a lateral cervical approach extending through the thyrohyoid membrane at the superior margin of the ala of the thyroid cartilage, with subperichondrial resection of a portion of the upper part of the ala. Through this 'window' the cyst can be completely excised, using short-term intubation to secure the airway postoperatively. [**/*]

LYMPHANGIOMA

Lymphangiomas are cystic malformations (sometimes termed cystic hygromas) that result from abnormal development of the lymphatic vessels. In the head and neck they may be macrocystic (usually infrahyoid), microcystic (usually suprahyoid) or a combination of the two. Occasionally, a microcystic lymphangioma may extend into the tongue base, valleculae and supraglottis, and airway obstruction may result. If the lymphangioma is very extensive a tracheostomy may be required, but where supraglottic involvement is less severe it may be possible to debulk the lesion by endoscopic vaporization using a CO₂ laser.⁹ [**/*]

BIFID EPIGLOTTIS

Bifid epiglottis is a rare laryngeal anomaly in which the epiglottis fails to fuse in the midline and thus has a cleft extending down to its tubercle. It may be seen as a feature of Pallister-Hall syndrome, the cardinal elements of which are hypothalamic hamartoblastoma, hypopituitarism, imperforate anus and postaxial polydactyly. It usually

presents with feeding difficulties due to aspiration and with stridor because of collapse and enfolding of the two halves of the epiglottis. Endoscopy establishes the diagnosis, and treatment options include amputation of the epiglottis and tracheostomy. [*]

Glottis

LARYNGEAL WEBS

Failure of complete canalization of the larynx during embryogenesis may result in a glottic or, very rarely, a supraglottic web. The majority involve the anterior glottis, fusing the vocal cords along a variable part of their length, and producing a correspondingly variable degree of respiratory obstruction and dysphonia (Figure 88.3). Characteristically there is inspiratory stridor and a rather weak, high-pitched, squeaky voice. The combination of a weak cry from birth and recurrent croup in infancy should always raise suspicion of a laryngeal web. Occasionally, a congenital posterior, interarytenoid web occurs, and may be associated with cricoarytenoid joint fixation.

Almost all anterior glottic webs are fairly thin posteriorly, close to their free border, but become progressively thicker anteriorly with increasing subglottic extension. This can make surgical treatment frustratingly difficult. Where the web is small and causing little in the way of symptoms it is usually best to leave well alone. A longer web may be divided endoscopically along the margin of one vocal cord with a knife or CO₂ laser; if it is very thin then subsequent endoscopic dilatation may be sufficient to permit stable healing without the web reforming. Usually, however, the web is quite thick anteriorly and it is then necessary to place an endoscopic keel in order to prevent recurrence. In the young child with a small larynx a covering tracheostomy is necessary for the two weeks that the keel is in place. Longer, thicker webs with an inadequate airway need to be managed initially with a tracheostomy, and can then be corrected at the age of three to four years via a laryngofissure with insertion of a keel. In cases where the airway is very small and there is associated subglottic stenosis a laryngotracheal reconstruction (LTR) with anterior cartilage grafting is required. This can be carried out in the infant as a single-stage procedure with postoperative endotracheal intubation to stent the larynx for approximately seven days. However, in practice, most infants with a severe glottic web will have a tracheostomy performed in which case the LTR can be advantageously deferred to the age of about two years, when the larynx is larger and the vocal cord dissection can be undertaken more precisely. [*]

LARYNGEAL ATRESIA

Laryngeal atresia is incompatible with life unless there is an associated tracheo-oesophageal fistula (TOF) which

permits ventilation via a tube in the oesophagus, or unless an emergency tracheostomy is performed in the delivery room. However, there are now cases being recognized antenatally on ultrasound imaging and managed with an extrauterine intrapartum treatment (EXIT) procedure, whereby a tracheostomy is undertaken following elective Caesarean section with the neonate still on placental circulation.¹⁰ [*]

CRI-DU-CHAT SYNDROME

This syndrome is primarily characterized by a cat-like mewing cry in infancy, microcephaly, downward-slanting palpebral fissures, mental retardation and hypotonia. It is caused by partial deletion of the short arm of chromosome 5. At endoscopy, observation during phonation reveals that the posterior part of the glottis remains open, giving it a diamond-shaped appearance. There is no respiratory embarrassment and the cry becomes less abnormal as the child grows older. [*]

VOCAL CORD PARALYSIS Causes

Vocal cord paralysis is the second most common congenital anomaly of the larynx after laryngomalacia.

It is worth noting that up to 45 percent of patients may have other, coexisting airway pathology, and so although outpatient flexible fiberoptic laryngoscopy may indicate the diagnosis, a formal microlaryngoscopy and bronchoscopy under general anaesthesia is nevertheless essential. [Grade B] Laryngeal ultrasound can be an accurate and reproducible method of assessing vocal cord movement, and may be useful in monitoring a child with known vocal cord palsy and in the diagnosis of the very sick child who may be unfit for endoscopy under general anaesthesia.¹¹ Approximately half of cases are unilateral and half bilateral.

Unilateral vocal cord paralysis is usually not congenital, most cases being acquired as a result of surgical injury to the left recurrent laryngeal nerve, often following correction of a congenital cardiac anomaly. The vocal cord lies in an intermediate position, and patients present with mild stridor, dysphonia and sometimes aspiration. Surgical intervention is not usually necessary, and the voice can be expected to improve as time passes and either recovery occurs or the other vocal cord compensates.

In contrast, bilateral vocal cord palsy is usually a congenital abductor paralysis. The vocal cords lie in the paramedian position with consequent inspiratory stridor, and a tracheostomy is necessary in approximately half of cases, most of which have other associated airway pathology. A classical cause of congenital bilateral vocal cord palsy is hydrocephalus with the Arnold-Chiari malformation. Once the diagnosis is made, prompt correction of the raised intracranial pressure with a shunt often improves vocal cord movement and a tracheostomy may thus be avoided. However, most cases of congenital bilateral vocal cord paralysis are idiopathic and the approach to management is greatly influenced by the fact that up to 58 percent will eventually recover, with 10 percent taking more than five years to do so and one reported case of recovery at the age of 11 years.¹² This strongly suggests that the problem is often one of delayed maturation in the vagal nuclei and argues convincingly in favour of a conservative management philosophy. Furthermore, where the airway is marginal it may become adequate with laryngeal growth alone, and glottic enlargement surgery in order to avoid a tracheostomy or achieve decannulation may improve the airway at the expense of the voice. [Grade B]

The infant with an inadequate airway and failure to thrive will require a tracheostomy. If vocal cord movement does not develop and the airway does not become adequate as a result of laryngeal growth, then an endoscopic laser cordotomy or arytenoidectomy should be considered at the age of eleven or over following a full discussion with the child and parents regarding the possible trade-off between airway and voice. If it is considered imperative to achieve decannulation earlier, perhaps because of poor social circumstances, then an endoscopic laser cordotomy can be attempted as early as

two years of age. If that fails then an external arytenoidectomy via a laryngofissure may be carried out at the age of four to five years with the prospect of an 84 percent decannulation rate;¹³ however, there is a small risk of aspiration as well as loss of voice quality and the procedure is irreversible. [*/**]

Subglottis

CONGENITAL SUBGLOTTIC STENOSIS

Congenital subglottic stenosis is due to defective canalization of the cricoid cartilage and/or conus elasticus, resulting in a small, elliptical, thickened cricoid and/or excessive submucosal soft tissue.¹⁴ Typically, there is gross thickening of the anterior lamina of the abnormal cricoid (Figure 88.4). Alternatively, there may be anterior fusion of the vocal cords with subglottic extension, as seen in 22q11 (Shprintzen) syndrome. Subglottic stenosis is said to be the third most common congenital anomaly of the larynx, but its true incidence is hard to determine because many patients are intubated in the neonatal period and are then considered by definition to have an acquired stenosis. The reality in this situation may be a combined congenital plus acquired stenosis. Milder degrees of

stenosis present as inspiratory or biphasic stridor as the child becomes older and more active, or as recurrent 'croup' owing to superimposed oedema from upper respiratory tract infections.

Diagnosis requires a microlaryngoscopy and bronchoscopy. The exact location of the stenosis with respect to the vocal cords, tracheostome and carina is measured and the number of normal tracheal rings above the tracheostome is counted. The degree of stenosis is measured by passing bronchoscopes, telescopes, endotracheal tubes, dilators or bougies of different sizes through the stricture. The Myer-Cotton grading system is widely used to classify paediatric laryngotracheal stenosis into four grades of severity.¹⁵ Grade I represents 0–50 percent obstruction, grade II 51–70 percent obstruction, grade III 71–99 percent obstruction and grade IV 100 percent obstruction. This helps to predict the outcome of surgical reconstruction.

If the airway is not severely compromised then surgery may not be required, especially as a congenital stenosis can be expected to enlarge with growth. Congenital cartilaginous stenosis represents a strict contraindication to dilatation or laser resection: any type of endoscopic treatment is liable to worsen the initial condition, and attempted dilatation is inevitably ineffective as the thickened ring of cricoid cartilage cannot be expanded.

If the airway is severely compromised then a tracheostomy is needed. This can sometimes be avoided in specialist centres where there are facilities for single-stage airway reconstruction in which an endotracheal tube is used as a stent, usually for a period of five to seven days.

The surgical options have evolved from the classical castellated laryngotracheoplasty designed by Evans and Todd¹⁶ in the early 1970s to achieve laryngeal framework expansion. This was superseded during the early 1980s by the LTR, devised primarily by Cotton.¹⁷ The LTR involves augmentation of the laryngotracheal complex by anterior and/or posterior midline incision of the cricoid with insertion of costal cartilage grafts to expand the airway. This technique has now been supplemented by the partial cricotracheal resection (PCTR) which was introduced into the paediatric age group by Monnier *et al.*¹⁸ in the early 1990s. This involves complete resection of the stenotic segment with end-to-end anastomosis of the tracheal stump to the thyroid cartilage.

Grade I subglottic stenosis usually requires no surgical intervention. Grade II stenosis can be reconstructed by means of an LTR with anterior cartilage grafting, generally without the need for a stent. Mild grade III stenosis is likely to need an anterior graft with posterior cricoid split supported by an endoluminal stent, and severe grade III stenosis (a pin-hole airway) requires both anterior and posterior grafts with stenting. Grade IV stenosis demands anterior and posterior grafts with prolonged stenting. For severe grade III and for grade IV stenosis, PCTR is an alternative technique with much to commend it. LTR

remains the last surgical option after failed PCTR if it is impossible to resect a further segment of trachea.

In cases of congenital subglottic stenosis, the LTR may be combined with submucosal resection of cartilage to 'core out' the thickened anterior cricoid ring. A similar submucous resection technique can be used via a laryngofissure for thick anterior glottic webs with subglottic extension. In both situations stenting is essential.

The least severe grades (I and II) have a better outcome than the most severe grades (III and IV). For PCTR, however, the grading system is not a predictor of success or failure, because the stenotic segment is completely resected. Results from the most experienced centres^{19, 20, 21} show a decannulation rate of just under 90 percent for grades I and II subglottic stenosis following LTR. However, this drops to approximately 80 percent for grade III and 50 percent or less for grade IV subglottic stenosis, implying the need for revision surgery in a significant number of cases. The latest results from the two centres with the largest experience in PCTR show a decannulation rate of 98 percent for primary surgery and 94 percent for salvage surgery after failed previous airway reconstruction.^{22, 23} [**/*]

For more detail on the management of laryngeal stenosis, the reader is referred to Chapter 89, Laryngeal stenosis.

SUBGLOTTIC HAEMANGIOMA

Infantile subglottic haemangioma is a capillary hamartoma which enlarges rapidly up to the age of about one year and then involutes slowly. Presentation with gradually increasing stridor peaks at the age of six weeks, with 85 percent presenting within the first six months of life. At endoscopy the typical appearance is of a compressible, pear-shaped red swelling in the subglottis on one side, left more commonly than right (Figure 88.5). Larger haemangiomas may be circumferential and, uncommonly, may extend down into the trachea or through its wall into the surrounding soft tissues of the neck or mediastinum. The appearance is so characteristic that biopsy is unnecessary; although in rare cases where there is doubt, biopsy can be undertaken without fear of troublesome bleeding because of the capillary nature of the lesion. If extension outside the airway is suspected, magnetic resonance imaging (MRI) is indicated. Subglottic haemangioma is life-threatening because of its situation in the narrowest part of the airway and if untreated carries a mortality rate of 50 percent.²⁴

Tracheostomy will maintain the airway until involution occurs. A review of the subject in 1984 by Sebastian and Kleinsasser²⁵ estimated that 50–70 percent of patients with airway haemangioma require a tracheostomy, and that children managed with tracheostomy alone could be decannulated at a mean age of 17 months. However,

© Hodder Arnold / Scott-Brown 7E

Figure 88.5 Subglottic haemangioma, showing a typical left-sided, pink pear-shaped swelling.

paediatric tracheostomy carries a mortality of 1–2 percent and a significant morbidity including delayed speech development.

Over the years, efforts have been made to develop alternative therapeutic strategies aimed at either maintaining the airway without recourse to tracheostomy, or at least shortening the period of cannulation. Any acceptable treatment must be at least as safe as tracheostomy and should be free of side effects, as there are no sequelae after natural involution, but these requirements have proved difficult to fulfil.

Radiotherapy delivered by low-dose external beam or gold-grain implant brings about involution within nine months, but has been abandoned because of concerns regarding possible induction of thyroid malignancy.

CO₂ laser vaporization can be effective but is probably only suitable for small lesions. In a ten-year review of experience at Boston Children's Hospital²⁶ it was found that tracheostomy could not be avoided in 30 percent of cases, and 18 percent developed subglottic stenosis. It would thus seem that conservative laser treatment of large haemangiomas fails to achieve involution, while vigorous application can result in cicatricial stenosis.

Systemic steroids produce dramatic regression of most subglottic haemangiomas. Complications of steroid therapy, such as growth retardation and Cushing's syndrome, can be reduced by alternate day dose regimens and intermittent courses, but treatment may be required for as long as 12–18 months.²⁷ Systemic steroids are, therefore, best reserved for use in short courses in order to maintain a good airway while definitive treatment is being planned.

Interferon alpha-2a has shown promising results in the treatment of patients with extensive, life-threatening airway haemangiomas who had failed steroid and/or laser therapy.²⁸ However, daily subcutaneous injections were required for a mean period of 11 months, and recognized side effects during interferon therapy include pyrexial reactions, elevated liver transaminases, neutropenia, thrombocytopenia, alopecia, neurotoxicity and growth retardation.

Intralesional steroid injection followed by intubation for seven days, repeated as necessary, was pioneered by Hoeve *et al.* at Sophia Children's Hospital in Rotterdam.²⁹ Overall, 14 of 17 patients (82 percent) treated by this method achieved a permanently adequate airway by a mean age of nine months, and no patient developed subglottic stenosis. However, a mean of six endoscopies followed by six periods (37 days) of intubation over a period of five months were needed in the infants treated with success, with a tendency for larger lesions to require longer periods of treatment. This puts a considerable strain on the intensive care resources of the hospital, and may test the parents' powers of endurance.

Submucosal excision of the haemangioma has been complicated by subglottic stenosis when attempted in the past. However, as Bailey *et al.*³⁰ have described, the problem can now be avoided by combining excision with a cricoid split to decompress and expand the subglottis. The airway is stented with an endotracheal tube for five to ten days postoperatively, and this enables the surgery to be carried out in a single stage without a covering tracheostomy. He feels that excision should be chosen as a primary treatment for large haemangiomas. It is less satisfactory as a secondary technique after other methods have failed, as scarring then makes submucosal dissection difficult and consequent mucosal damage makes stenosis more likely.

In conclusion, very small haemangiomas may not require treatment, or may be amenable to CO₂ laser vaporization. Medium-sized lesions seem suitable for intralesional steroids and intubation, but large ones are probably best managed by primary submucous resection. [Grade C] Very large haemangiomas, and especially those which are circumferential or in which MRI shows extension down into the trachea and/or through the tracheal wall into the surrounding tissues, must carry a greater risk of stenosis developing after surgery and may be more safely dealt with by performing a tracheostomy and awaiting spontaneous involution. [**/*]

LARYNGEAL AND LARYNGOTRACHEOESOPHAGEAL CLEFT

Posterior laryngeal clefts result from failure of the posterior cricoid lamina to fuse, and in the more extensive laryngotracheoesophageal clefts there is also incomplete development of the tracheoesophageal septum. The classification devised by Benjamin and Inglis³¹ has been widely adopted because it relates well to

symptoms and treatment. A type I cleft may extend down to the level of the vocal cords; a type II cleft extends below the vocal cords into the cricoid (Figure 88.6); a type III cleft extends down into the cervical trachea; and the, fortunately rare, type IV cleft extends into the thoracic trachea and may even reach the carina. Approximately 25 percent of patients with a laryngeal cleft will also have a TOF, but conversely the incidence of laryngeal cleft in patients with a TOF is low. Abnormalities of the tracheal ring structure in cleft patients may result in associated tracheomalacia, which can add to the difficulties of management.

The majority of laryngeal cleft patients have associated congenital abnormalities, of which TOF is the most common. These may include tracheobronchomalacia, congenital heart disease, dextrocardia and situs inversus. Often there is severe gastro-oesophageal reflux. Laryngeal clefts are characteristic of two syndromes: the Opitz-Frias syndrome (G syndrome) comprises hypertelorism, cleft lip and palate, laryngeal cleft and hypospadias; Pallister-Hall syndrome (described earlier in relation to bifid epiglottis) consists of congenital hypothalamic hamartoblastoma, hypopituitarism, imperforate anus and post-axial polydactyly, and may include a laryngeal cleft.

As might be expected, symptoms become more severe the longer the cleft. Type I clefts present with cyanotic attacks on feeding and recurrent chest infections. Stridor (similar to that of laryngomalacia) may be a feature, secondary to prolapse of the cleft edges into the airway. The differential diagnosis for infants presenting with these symptoms includes gastro-oesophageal reflux, neuromuscular incoordination of deglutition, vocal cord paralysis, raised intracranial pressure and TOF. Types II and III clefts produce dramatic aspiration with recurrent

Figure 88.6 Laryngeal cleft (type II). Reused with permission from Bailey CM. Congenital disorders of the larynx, trachea and bronchi. In: Graham JM, Scadding GK and Bull PD (eds). *Pediatric ENT* (in press), with kind permission of Springer Science and Business Media.

pneumonia, sometimes with stridor and an abnormal cry. Type IV clefts cause severe aspiration, cyanosis and incipient cardiorespiratory failure.

Investigation of the child with aspiration and stridor requires a careful microlaryngoscopy and bronchoscopy; no other diagnostic method can replace it. Suspension microlaryngoscopy allows the use of two probes to part the arytenoids, and without this manoeuvre the diagnosis may be missed as redundant mucosa tends to prolapse into the defect and obscure it. A plain chest x-ray may show changes secondary to recurrent aspiration pneumonia. A lateral neck x-ray may demonstrate vaguely increased laryngeal soft tissue and the nasogastric feeding tube may be seen protruding anteriorly into the airway. Videofluoroscopic contrast swallow studies may not differentiate laryngeal incompetence from neuromuscular incoordination, and a high index of suspicion is required.

The approach to treatment depends entirely upon the length of the cleft. A short type I cleft with no aspiration requires no treatment. Minimal aspiration may be managed by thickening the feeds. Significant aspiration requires endoscopic repair of the cleft in two layers, using a nasogastric feeding tube until the suture line has healed. A very short type II cleft may also be repaired endoscopically, albeit with difficulty, using a nasogastric tube. However, a long type II or a type III cleft needs to be approached anteriorly through an extended laryngofissure with a low tracheostomy to cover the procedure; a nasogastric tube will tend to erode through the suture line, and so a gastrostomy is required (usually combined with a Nissen fundoplication to control reflux reliably). These children take many months to learn to swallow after successful cleft repair and thus long-term gastrostomy feeding is necessary. Surgical repair of the cleft is undertaken in three layers in an effort to optimize healing: the two mucosal layers are reinforced by an interposition graft of tibial periosteum or temporalis fascia. The type IV cleft presents an altogether more difficult surgical challenge. Owing to the length of the cleft a tracheostomy is unhelpful in stabilizing the airway, and the convexity of the tube would tend to erode through the party wall suture line; the repair must therefore be undertaken using a single-stage technique with endotracheal extubation taking place seven to ten days postoperatively. Short type IV clefts may be managed by an anterior approach through a cervical incision, if necessary pulling the trachea up into the neck to reach the lower end of the cleft. Longer clefts will require a lateral cervical approach in combination with a thoracotomy, or preferably an anterior cervicothoracic approach via a median sternotomy with repair on extracorporeal membrane oxygenation (ECMO) or cardiopulmonary bypass. Postoperatively, tracheomalacia may prevent extubation and so a tracheostomy may be needed once the cleft has healed soundly.³²

Mortality remains significant, being approximately 14 percent overall,³³ rising to 66 percent for type IV

laryngotracheoesophageal clefts and up to 100 percent for full-length clefts ending at the carina.³⁴ A large proportion of the mortality is from causes unrelated to the cleft, and notable morbidity is produced by other associated congenital abnormalities and often by delay in reaching the correct diagnosis. Management should be in a major paediatric centre where a full multidisciplinary team is available with full neonatal and paediatric intensive care facilities. [**/*]

TRACHEA AND BRONCHI

Agenesis

Tracheal agenesis may be complete (full-length) or partial, but in either case there is no continuity between the larynx and the bronchi. Occasionally, short-term survival may be possible if there is a broncho-oesophageal fistula, which can permit some airflow into the lungs, but surgical efforts to use the oesophagus as a tracheal replacement have not been successful and long-term survival has not proved possible. The majority of cases are complicated by other severe congenital abnormalities.

Agenesis of one main bronchus and its associated lung is not as rare as tracheal agenesis and is compatible with survival, although such children often have coexisting congenital anomalies and are at risk from chest infections because of their much-reduced respiratory reserve. Bilateral bronchial and pulmonary agenesis is extremely rare and is, of course, fatal. Occasionally, localized atresia occurs in a peripheral bronchus resulting in a distal mucocoele which may need to be resected if it is causing severe compression of the surrounding lung. [*]

Stenosis

Occasionally, a membranous web may be encountered in the trachea with a normal underlying cartilaginous ring structure. Such cases usually fare well with endoscopic rupture and dilatation. Thicker congenital fibrous stenoses may be amenable to radial KTP laser incision and balloon dilatation, followed by application of mitomycin C to reduce the risk of restenosis.³⁵

Longer-segment congenital tracheal stenosis is generally due to complete tracheal rings which are fused posteriorly, and may be fused together to form a cartilage plate. This poses a much more severe reconstructive challenge. Such a stenosis may be of variable severity and length. It may involve almost the entire length of the trachea ('stove-pipe trachea' or 'microtrachea'), just the distal part with a funnel-like stenosis maximal at the carina or only a short segment. Long-segment congenital tracheal stenosis, involving more than 50 percent of the trachea, is often associated with a pulmonary artery sling

(25 percent), intracardiac lesions (20 percent) and right-sided aortic arch.³⁶ As recently as 35 years ago this abnormality was fatal.

Children with congenital tracheal stenosis usually present with respiratory distress within the first year of life. Symptoms may become apparent in the neonatal period if the stenosis is severe but frequently, presentation is delayed until the infant is several months old when greater physical activity makes increasing demands upon the respiratory system. Biphasic stridor or wheezing is the cardinal symptom, but sometimes difficulty in breathing develops rapidly as a result of a respiratory tract infection, with consequent oedema and increased secretions. In this situation the child may require endotracheal intubation, and it is then found that only a very small-sized tube can be passed. In the case of a long tapering stenosis, which may narrow virtually to a pin-hole, this is a dangerous situation. The tube tip tends to impact into the stenosis, granulations begin to develop and obstruct the already perilous airway, and endoscopic evaluation is then a procedure fraught with difficulty. In such cases the stenosis often seems surprisingly severe considering the child's mild symptoms prior to the precipitating illness.

A chest x-ray is a basic requirement to see whether there are any signs of bronchial obstruction producing collapse or atelectasis. In the unintubated child, the trachea and main bronchi were traditionally well seen on a Cincinnati x-ray, which is a high-kilovolt filter view of the mediastinum giving good air/soft tissue definition. Modern 'digitally enhanced' radiography has, however, made this technique somewhat obsolete as it can show such fine detail (see Chapter 102, Imaging in paediatric ENT). An echocardiogram is essential to exclude a vascular ring in view of the high incidence of associated anomalies of the heart and great vessels. Computed tomography (CT) or MRI is often helpful to assess further the vascular anatomy and its relationship to the trachea, but angiography is now rarely indicated and both three-dimensional reformatted CT and CT 'virtual bronchoscopy' have significant shortcomings. In the hands of a skilled paediatric interventional radiologist, contrast bronchography is the most valuable imaging modality and is currently preferred to CT or MRI. It will show the size of the tracheal lumen and outline the trachea and bronchi distal to the stenosis which may be too narrow to permit passage of a bronchoscope (Figure 88.7). Bronchography is carried out under general anaesthesia, and a preliminary endoscopic assessment can be undertaken at the same time using a slim flexible fibre optic bronchoscope passed through the endotracheal tube.

Endoscopy remains the 'gold standard' investigation for a child with stridor. For tracheal stenosis, rigid endoscopy using a ventilating bronchoscope system is the best method. However, great care must be taken not to traumatize the stenosis by attempting to pass a bronchoscope that is too large, or the resultant oedema may convert an airway that is just adequate into one that is

Figure 88.7 Tracheal stenosis: bronchogram of a long-segment lower tracheal stenosis with associated stenosis of the main bronchi and with a 'pig' bronchus at its upper end.

not. On occasions, the airway is so perilous that endoscopy carries a real risk of precipitating complete airway obstruction. In such a situation definitive surgery can be planned upon the basis of the imaging results and endoscopy performed immediately prior to opening the chest, with standby facilities ready for cardiopulmonary bypass. Frequently, the stenosis is too narrow to permit passage of even the smallest (size 2.5) bronchoscope, and it is necessary to use the unsheathed 1.9 mm telescope to survey the length of the narrow segment and assess the state of the distal trachea, carina and bronchi. Sometimes the airway is too narrow to admit even this extra-slim telescope, and then the surgeon must rely on contrast bronchography.

Mild cases with minimal symptoms may require no intervention after the diagnostic endoscopy, as the trachea can grow and there may be only slight limitation of exercise tolerance. Certainly, patients who can be managed conservatively should be, as surgical treatment is difficult and carries a substantial mortality and morbidity.

Successful endoscopic balloon dilatation of long-segment tracheal stenoses has been reported, producing a posterior split in the complete tracheal rings and increased airway lumen maintained over several years following a period of stenting with an endotracheal tube. However, it is difficult to see why the airway does not quickly close down again to its original size, as the 'spring' in the cartilage is not broken by splitting it in just one place and fibrosis is bound to occur at the site of the split.

Nevertheless, balloon dilatation is a useful adjunctive treatment modality for granulations and fibrous stenoses such as may develop postoperatively at the site of an anastomosis.

Very narrow, short segments can be excised with end-to-end anastomosis. The excised segment of tracheal cartilage may be used as a free autograft at the anastomotic site, and this method permits a longer section to be removed with less tension upon the suture line. For longer stenoses slide tracheoplasty is an advantageous technique^{37,38} as it minimizes shortening of the trachea and hence reduces anastomotic tension. The oblique anastomosis also seems less liable to postoperative stenosis than an end-to-end anastomosis. The tracheoplasty is performed by dividing the stenosis at its midpoint, incising the proximal and distal narrowed segments vertically on opposite anterior and posterior surfaces and sliding these together. The stenotic segment is thus shortened by half, the circumference is doubled, and the luminal cross section quadrupled. Long resections may require a laryngeal drop and/or hilar release to avoid undue tension upon the suture line.

The most difficult problem remains the full-length 'stove-pipe' microtrachea, especially when the carina and bronchi are involved. As might be expected, the narrower the stenosis, the more difficult the reconstruction. Augmentation tracheoplasty can be achieved by anterior costal cartilage grafting (with posterior division of the complete rings if necessary). Alternatively, a pericardial flap or free patch can be employed, suspended by supporting sutures to adjoining mediastinal structures and stented by an endotracheal or extended tracheostomy tube for as long as it takes to become stiff and self-supporting. If the stenosis is extremely severe with only a pin-hole lumen, then cartilage grafting (even with a posterior split) cannot be expected to achieve an adequate airway, and a large suspended pericardial patch is needed; however, the larger the patch, the greater the risk of subsequent tracheomalacia. Such surgery is best undertaken using a neck incision and median sternotomy with cardiopulmonary bypass and a joint cardiothoracic-ENT surgical team. Any coexisting anomaly of the heart or great vessels should usually be corrected at the same time. ECMO may sometimes be useful to stabilize the patient's condition postoperatively as a 'bridge' between bypass and ventilation, and occasionally ECMO may be needed for preoperative support. The postoperative care of these patients is demanding, and a somewhat stormy course is not uncommon. The overall mortality associated with costal cartilage or pericardial patch tracheoplasty is substantial, ranging up to nearly 50 percent in the literature review by Andrews *et al.*³⁹ in 1994, but more recent experience in major centres has halved this figure. Involvement of the carina or either main-stem bronchus in the stenosis makes reconstruction much more difficult, and mortality and morbidity correspondingly increase.

An alternative is to use a cadaver tracheal homograft for the reconstruction, a technique pioneered by Herberhold in adults and later adopted for use in children.⁴⁰ It is our current policy to hold in reserve homograft reconstruction as a salvage technique for those children with life-threatening long-segment tracheal stenosis who have already failed conventional surgery.

The variety of reconstructive options available for treating tracheal stenosis in children means that the surgery must be individually tailored to the patient. A multidisciplinary tracheal team is required with a team coordinator/case manager, working in a major paediatric centre with full intensive care facilities.⁴¹ [Grade C] The difficulties involved mean that this uncommon problem remains a challenge for even the most experienced paediatric cardiothoracic surgeon and otolaryngologist.

Bronchial webs may be ruptured with a bronchoscope or by balloon dilatation. Stenosis of a main bronchus is often associated with an adjoining vascular anomaly, and segmental resection with end-to-end anastomosis may be necessary. [**/*]

Tracheomalacia and bronchomalacia

Tracheomalacia is a condition in which there is reduced stiffness of the tracheal wall, resulting in abnormal collapse of the trachea during expiration which, if severe, can produce symptoms of airway obstruction. Bronchomalacia is the equivalent condition affecting the bronchi. There is, however, no association between tracheobronchomalacia and laryngomalacia, although because the latter is a common condition it may sometimes coexist.

Pathologically, the striking finding is an increased muscle-to-cartilage ratio seen on the transverse section of the trachea; in other words, a widening of the trachealis relative to the cartilage rings, which become C shaped instead of horseshoe shaped. Normally, the ratio is 1:4 or 1:5, but in tracheomalacia it may be closer to 1:2. However, in children the trachea and bronchi are more compliant than in the adult and some degree of collapse may be observed during endoscopy in normal children. This is particularly obvious if the level of general and topical anaesthesia is too light and the child tends to cough and strain in consequence, often with anterior bulging of the trachealis. To be clinically significant, more than 50 percent obstruction is probably required, as visualized at the end of expiration in the well-anaesthetized child.

Tracheomalacia is traditionally classified as **primary** (idiopathic), due to an intrinsic abnormality in the wall of the airway, or **secondary**, due to another associated anomaly or to external compression. The primary form is less common and tends to affect a longer segment of the airway. Secondary tracheomalacia is usually more localized and may be associated with TOF, laryngeal cleft or with extrinsic compression by an anomaly of the great vessels or a mediastinal mass. A common but special form

of localized secondary tracheomalacia is the suprastomal collapse which arises above most long-standing paediatric tracheostomies, produced by pressure from the convexity of the tracheostomy tube.

The stridor of tracheomalacia becomes apparent during the first few weeks of life and consists of a very variable high-pitched expiratory noise. This may be accompanied by a harsh, barking cough, especially in the localized form of the condition. Characteristically, the stridor becomes much worse when the child is active, feeding, upset, coughing or crying, and may be associated with cyanotic attacks which are sometimes sufficiently severe to be termed 'dying spells'. The pathophysiology of these seems to be that with vigorous respiration, airflow through the trachea increases and in accordance with Bernoulli's principle the pressure within the airway correspondingly falls. This encourages further collapse of the malacic segment and a vicious circle is established that can result in complete collapse of the trachea with respiratory obstruction. These episodes are probably self-limiting but, faced with total obstructive apnoea and cyanosis, parents and caregivers will usually attempt resuscitation rather than wait and see.

The stridor of tracheobronchomalacia is typically episodic, thus on examination the child may seem perfectly well. There may be a prolonged expiratory phase to respiration, possibly with faint expiratory stridor. However, crying or feeding can dramatically change the picture to one of an infant who is clearly obstructed and in respiratory distress.

Plain x-rays are not usually helpful. A barium swallow may identify a vascular ring or TOF and can also demonstrate the airway collapse on lateral screening. Echocardiography is useful in defining any suspected anomaly of the heart and great vessels. CT and MRI are of limited value, and the most useful radiological investigation is contrast bronchography. This not only demonstrates the areas of collapse but enables the opening pressures to be measured, which is extremely helpful in setting continuous positive airway pressure (CPAP) levels for children with very severe tracheobronchomalacia who are intubated or have undergone tracheostomy. Even if tracheobronchomalacia has been demonstrated radiologically it is nonetheless important to undertake a full airway endoscopy to examine the collapse directly and exclude other abnormalities such as a TOF or laryngeal cleft. However, endoscopy presents traps for the inexperienced in the assessment of tracheobronchomalacia.⁴² Overdiagnosis can happen, as mentioned earlier, under conditions of poor anaesthesia which allow coughing. Underdiagnosis is a risk either from mechanical splinting of the trachea by the bronchoscope or by positive end-expiratory pressure applied by the anaesthetist. Typically, anterior tracheal wall collapse will be observed, with flattened tracheal rings and a wide trachealis (Figure 88.8). In addition, the common vascular anomalies have sufficiently characteristic features to aid diagnosis (see below).

© Hodder Arnold / Scott-Brown 7E

Figure 88.8 Severe tracheomalacia.

Mild tracheobronchomalacia (less than 75 percent collapse) requires no intervention, and the stridor can be expected to resolve spontaneously by around the age of two years. However, parents will require careful explanation and reassurance, as well as being taught cardiopulmonary resuscitation if their child is prone to 'dying spells'. Severe tracheobronchomalacia (more than 75 percent collapse) may require treatment. If it is secondary to a vascular anomaly this should be corrected. The severe localized tracheomalacia often associated with a TOF usually responds well to an aortopexy, whereby the aorta is sutured to the back of the sternum. If this fails then an extended tracheostomy tube will effectively support a midtracheal malacic segment, but this is not a satisfactory solution for lower-end tracheal or for bronchial collapse. For the infant in intensive care with severe primary tracheobronchomalacia who cannot be weaned off CPAP, it may be necessary to resort to a tracheostomy in order to apply long-term CPAP, sometimes for a period of 12 months or more. Alternative surgical solutions for this most severe end of the disease spectrum have been sought by cardiothoracic surgeons: these include internal or external stenting of the trachea, segmental resection and cartilage grafting, but all present formidable difficulties and complications with very variable outcome and the risks may exceed those of the condition itself. [**/*]

Tracheo-oesophageal fistula

Tracheo-oesophageal fistula is a fairly common congenital malformation of the neonatal air and food passages, which usually occurs in association with oesophageal atresia. Eighty-seven percent of cases have oesophageal atresia

with a TOF communicating between the distal oesophagus and the mid- to lower trachea or a main bronchus. The remainder have oesophageal atresia without a TOF (6 percent); atresia with a proximal TOF (2 percent); atresia with a proximal and distal TOF (1 percent); or a TOF without atresia ('H-type fistula') (4 percent). Approximately 50 percent of infants with TOF have additional congenital malformations, and 10–20 percent have tracheomalacia (see Chapter 101, Diseases of the oesophagus, swallowing disorders and caustic ingestion).

Children who present to the paediatric otolaryngologist are invariably those with an H-type fistula. Since there is no oesophageal atresia they are the least symptomatic of the group, with no swallowing difficulty, but small amounts of fluid pass through the fistula into the trachea and produce symptoms and signs of recurrent minor aspiration. The diagnosis is usually established by a barium swallow, but even thin contrast may not pass through a tiny fistula. In such cases bronchoscopy is required to identify the tracheal opening, which is typically characterized by a V-shaped mucosal fold around it in the posterior wall of the trachea (**Figure 88.9**). Usually the fistula is too small to allow passage of a fine spaghetti suction catheter, but methylene blue introduced into the oesophagus will be seen to seep into the trachea at this point. Treatment is by ligation and division of the fistula. [**/*]

For further details on the management of TOF, the reader is referred to Chapter 101, Diseases of the oesophagus, swallowing disorders and caustic ingestion.

Vascular compression

It is estimated that 3 percent of the population have an anomaly of the great vessels, but only a few of these have

symptomatic airway compression.⁴³ Such vascular anomalies are classified into vascular rings which completely encircle the trachea and oesophagus and vascular slings which exert noncircumferential pressure.

VASCULAR RING

The commonest vascular ring is a double aortic arch. In this abnormality the ascending aorta divides into two arches, one of which passes to the right of the trachea and the other to the left, reuniting posterior to the oesophagus to form the descending aorta on the left. The left arch is usually smaller than the right, and the configuration of the main branches is variable, but the result is compression of both the trachea and oesophagus producing stridor, dyspnoea, dysphagia and a brassy cough.

A less common and less constricting ring is produced when there is a right-sided aortic arch and descending aorta associated with an aberrant left subclavian artery. In this situation the ring is completed by the ligamentum arteriosum which passes to the left of the trachea, connecting the descending aorta to the pulmonary trunk.

Patients with vascular rings tend to present earlier in life than those with vascular slings and with more severe airway symptoms. A barium swallow is diagnostic, showing a characteristic double impression upon the column of contrast, and an echocardiogram will confirm the anomaly. Surgical treatment, almost always necessary, is by dividing the lesser component of the ring, but there is invariably a localized area of tracheomalacia produced by the compression which may persist for months or even years.

VASCULAR SLING

The commonest vascular sling is an aberrant innominate artery. The artery arises further to the left and more posteriorly than usual, and crosses the anterior surface of the trachea obliquely just above the carina from the left inferiorly to the right superiorly.

Cases usually present during the first year of life with less severe airway obstruction than that caused by vascular rings. Typically, there is expiratory stridor, cough, recurrent chest infection and sometimes reflex apnoea. The bronchoscopic appearances are diagnostic, with a characteristic sloping, pulsatile compression of the trachea 1–2 cm above the carina which is most marked on its anterolateral aspect. Upward pressure with the tip of the bronchoscope compresses the artery against the sternum and obliterates the right radial pulse. In severe cases, surgical relief of the obstruction is necessary: this can be achieved either by arterioplexy, in which the vessel is suspended anteriorly from the sternum, or by reimplanting it further to the right on the aortic arch.

A 'pulmonary artery sling' is produced by an anomalous left pulmonary artery, which arises on the right and passes between the trachea and oesophagus, compressing both (**Figure 88.10**). This may be associated with lower-end tracheal stenosis which sometimes also involves the carina and right main bronchus. Surgical reanastomosis may be needed to relieve the compression.

Enlargement of the pulmonary artery in association with a cardiac defect can also produce compression of the distal trachea and bifurcation. An aberrant right or, more rarely, left subclavian artery passing posterior to the oesophagus will compress the oesophagus alone, and so produces dysphagia but no stridor. [**/*]

Anomalous bifurcations

The right upper lobe bronchus may take origin from the right lateral wall of the trachea above the carina, and is then often termed a 'pig bronchus'. It is usually an asymptomatic, incidental finding, but may sometimes be

associated with tracheal stenosis. Minor alterations to the distal bronchial branching pattern are not unusual and, likewise, do not usually cause problems.

Congenital cysts and tumours

Tracheogenic and bronchogenic cysts are thought to originate from evaginations of the primitive tracheal bud, and are sometimes termed reduplication anomalies. They may happen anywhere along the tracheobronchial tree: they are lined with respiratory epithelium, filled with mucus, and their walls may contain any elements of normal tracheobronchial wall. Bronchogenic cysts may communicate with the airway.

Some patients are symptom-free, but large cysts or those that become infected cause nonpulsatile compression of the airway and present with symptoms, signs and endoscopic appearances otherwise similar to those produced by vascular compression (see Vascular compression above). CT or MRI will demonstrate the lesion clearly, and treatment is by thoracotomy and surgical excision.

Thymomas or teratomas may produce airway compression in the neck or mediastinum. CT or MRI is needed to define the size and situation of the mass prior to surgical excision. [*]

KEY POINTS

- Investigation of the child with aspiration and stridor requires a careful microlaryngoscopy and bronchoscopy; no diagnostic method can replace it.
- In laryngomalacia (the most common congenital cause of stridor) the stridor is usually improved immediately following aryepiglottoplasty.
- Anterior glottic webs are thin posteriorly, but become progressively thicker anteriorly. This can make surgical treatment frustratingly difficult.
- In the EXIT procedure, tracheotomy is undertaken with the foetus still on placental circulation.
- Endoscopy presents traps for the inexperienced in the assessment of tracheobronchomalacia.
- The use of endoscopy to diagnose many of the conditions described in this chapter is dependent on skilled paediatric anaesthesia.
- Management of congenital disorders of the larynx, trachea and bronchi requires the multidisciplinary resources of a major children's centre.

Best clinical practice

- ✓ The diagnosis of mild laryngomalacia can be confirmed in the outpatient clinic by flexible fiberoptic laryngoscopy.
- ✓ Microlaryngoscopy and bronchoscopy under general anaesthesia is necessary if the stridor in laryngomalacia is severe, there is failure to thrive or any atypical features.
- ✓ Although outpatient flexible fiberoptic laryngoscopy may indicate the diagnosis of vocal cord palsy, a formal microlaryngoscopy and bronchoscopy under general anaesthesia is essential to exclude coexisting airway pathology.
- ✓ Small subglottic haemangiomas may not require treatment, or may be amenable to CO₂ laser vaporization. Medium-sized lesions seem suitable for intralesional steroids and intubation, but large ones are probably best managed by primary submucous resection.
- ✓ In tracheal stenosis the airway may be so perilous that endoscopy carries a real risk of precipitating complete obstruction.

Deficiencies in current knowledge and areas for future research

- The rarity and often life-threatening nature of many congenital disorders of the larynx, trachea and bronchi means that evidence for their management tends to be confined to evidence levels 3 and 4. It is hard to see how this can be overcome without increased central referral of these challenging cases to just a few major paediatric centres. Even so, international collaboration between such centres is often the only way to generate sufficient patient numbers just for evidence level 3 studies in this field.
- One potentially fruitful area for future study lies in an assessment of the efficacy of mitomycin C in reducing restenosis following airway reconstructive surgery.⁴⁴ Since it is an adjunctive therapy it is possible to undertake a prospective, randomized, double-blind placebo-controlled trial of its use, and this has already been attempted on a small scale, but with inconclusive results.⁴⁵

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words paediatric, laryngeal, subglottic, glottic, posterior glottic, web, supraglottic, stenosis; laryngotracheoplasty; laryngotracheal reconstruction; and cricotracheal resection. The focus is on evaluation, management and surgery.

INTRODUCTION

Over the past 40 years, there has been a marked evolution in the presentation and management of paediatric laryngeal stenosis. Prior to 1965, this diagnosis indicated the presence of a congenital anterior glottic web or congenital subglottic stenosis. In many children, congenital subglottic stenosis could be anticipated to improve with time, even if placement of a temporary tracheotomy tube was required. The advent of prolonged intubation, particularly of the neonate, strikingly changed this situation. Acquired subglottic stenosis became and currently remains the most frequent cause of laryngeal stenosis. This condition is generally more severe than congenital subglottic stenosis and does not improve with time. Modern paediatric laryngeal reconstruction was thus born of necessity to manage these otherwise healthy, but tracheotomy-dependent children.

Further improvements in neonatal care, particularly the use of nasopharyngeal continuous positive airway pressure (CPAP), led to a significant decline in the incidence of acquired subglottic stenosis in children

without other medical problems. The evolution of neonatal care has resulted in the salvage of premature and often medically fragile children whose laryngeal pathology is but one component of a myriad of health issues. The overall care of such children is more complex to manage, ideally requiring an interdisciplinary team approach. In addition, their laryngeal pathology is more severe, with stenosis potentially involving not only the subglottis but also the supraglottis or glottis. While subglottic stenosis is far more common than glottic or supraglottic stenosis, it is not uncommon for combined pathology to be seen.

Laryngeal stenosis continues to cause significant morbidity and mortality, whether or not patients are tracheotomy dependent. The primary aim of intervention is decannulation or preventing the need for tracheotomy. In selected patients, voice restoration or provision of a safer airway is the primary consideration, with decannulation being a secondary goal.

These children are primarily cared for in paediatric centres where management has evolved in response to experience and as determined by the needs of the

individual child. For many of the strategies described, randomized controlled trials are neither appropriate nor available, hence the evidence levels presented for the recommendations in this chapter are largely 3 and 4.

PAEDIATRIC LARYNGEAL ANATOMY

Compared with the adult larynx, the infant larynx lies high in the neck, with the hyoid bone overriding its superior aspect. The narrowest point in the infant airway is the cricoid ring. Since this is the only fixed ring within the airway, it is the most vulnerable point for iatrogenic damage caused by intubation. In a term newborn, the diameter of the subglottis is between 4.5 and 5.5 mm. If the airway diameter in the term newborn is less than 4 mm, subglottic stenosis is present. A useful guideline is that the outer diameter of a 3.0 mm endotracheal tube is 4.2 mm.

The superior margin of the supraglottis comprises the superior edge of the epiglottis, the aryepiglottic folds and the arytenoids, while the inferior margin is at the level of the true vocal folds. The glottis comprises the true vocal folds and the glottic chink. In the infant, the posterior 50 percent of the true vocal fold consists of the vocal process of the arytenoid. The subglottis lies between the under-surface of the vocal fold and the lower border of the cricoid cartilage. The subglottic mucosa is lined with respiratory epithelium. A transition to squamous epithelium occurs at the free edge of the true vocal fold.

EVALUATION

History

A child with laryngeal stenosis may present with stridor, extubation failure or tracheotomy dependency. In each of these clinical scenarios, a meticulous initial history forms the basis for further evaluation and investigation. It is important for clinicians to determine the overall health status of the child, exploring signs or symptoms and being aware of a past diagnosis of gastro-oesophageal reflux, aspiration, lung disease or cardiac disease.

In a child presenting with stridor, the duration of stridor must first be ascertained. If acute, stridor is a medical emergency. When it is more chronic, its mode of onset should be ascertained and the determination of whether it is stable or progressive should be made. In addition, the degree of compromise to the child's lifestyle should be assessed, particularly with regard to exercise intolerance and shortness of breath on exertion. Some children will also experience obstructive symptoms during sleep. These symptoms are usually associated with supraglottic pathology although they may be indicative of a second nonlaryngeal pathology such as adenotonsillar hypertrophy. The aetiology of the child's compromised

airway should also be sought, in particular, any prior history of intubation. If there has been such a history, relevant details such as the duration of intubation, the temporal relationship between intubation and the onset of airway symptoms, and whether an age-appropriate endotracheal tube was used should be determined.

The reason for intubation should be assessed, as should any medical problems that could contribute to extubation failure. The relevant history should include the length of time the child was intubated, the size of the endotracheal tube, the number of attempts at extubation and whether extubation failure abruptly occurred following endotracheal tube removal or was due to gradual and progressive respiratory compromise necessitating reintubation.

In a child with tracheotomy dependency, the aetiology requiring initial placement of a tracheotomy should be ascertained and the duration of cannulation and size of the tracheotomy tube should be determined. Any history of airway reconstruction surgery is also extremely important. Another significant aspect of a thorough assessment is an evaluation of voice quality and the ability to tolerate a speech valve.

Physical examination

Once a case history has been taken, the presence of stridor and retractions at rest should be assessed. The nature of the stridor, in particular whether it is purely inspiratory, expiratory or biphasic, should be noted. Assessment of voice quality is particularly important in that it may provide an indication of the anatomic region of the pathology. Children with supraglottic stenosis usually present with a characteristic muffled or 'throaty' voice, while those with anterior glottic webbing tend to have a very hoarse voice. Those with posterior glottic stenosis and subglottic stenosis usually have normal voice quality. In a child presenting with extubation failure, nonlaryngeal causes such as nasal obstruction and glossoptosis are explored. In cases of tracheotomy dependency, the size of the tracheotomy tube, the child's ability to tolerate a speech valve and the possibility of tracheotomy tube plugging are pursued.

Imaging studies

Radiologic evaluation of the paediatric airway is most helpful in patients who are neither intubated nor tracheotomy dependent. Imaging studies fall into two time-related categories: those that are performed prior to endoscopic evaluation and those that are best after endoscopic evaluation. Prior to endoscopy, soft tissue airway films of the neck and chest should be performed in both lateral and anterior/posterior projections. These are useful in evaluating laryngeal stenosis and may also give timely warning of a possible tracheal stenosis. Anterior/

posterior and lateral chest films indicate possible underlying lung pathology. A barium swallow study may not only provide information on the ability to swallow and the relative risk of aspiration but may also indicate the need to evaluate the airway for a posterior laryngeal cleft or a tracheo-oesophageal fistula. In addition, it may provide information on a child's propensity to gastro-oesophageal reflux, vascular compression of the airway and the presence of an oesophageal foreign body.

After endoscopic airway evaluation, more directed imaging studies are valuable. Spiral computed tomography (CT) scanning of the airway with contrast enhancement provides a useful view of intrathoracic vasculature. Although both magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) also provide excellent views of intrathoracic vascular anatomy, they require more time to perform and are more likely to require sedation or anaesthesia. In younger children CT and MRI airway evaluation may complement endoscopic evaluation, but nevertheless cannot be considered definitive (see Chapter 102, Imaging in paediatric ENT).

In children with upper airway compromise, sleep fluoroscopy or cine magnetic resonance may provide a valuable dynamic airway assessment.

Endoscopic airway evaluation

FLEXIBLE NASOPHARYNGOSCOPY

In a child who has not been evaluated previously, flexible nasopharyngoscopy with the child awake should be performed prior to rigid endoscopy. The nasal passages, nasopharynx, oropharynx, supraglottic and glottic airway should be assessed, and pathology such as choanal atresia, adenoid hypertrophy, tonsillar hypertrophy, laryngomalacia and vocal cord paralysis should be excluded. To avoid the risk of inducing laryngospasm, the nasopharyngoscope should not be advanced below the level of the glottis. Although the precise mechanism is unclear, laryngospasm may happen even in children with bilateral true vocal cord paralysis.

RIGID ENDOSCOPY

It must be emphasized that evaluation of the paediatric airway should not be considered a minor procedure, particularly when performed in a child with an unstable airway (see Chapter 86, Stridor). Extreme care must be taken not to exacerbate the child's condition. The surgical and anaesthetic team must work together closely and must have specific knowledge of the paediatric airway and of appropriate instrumentation. In a child with a compromised airway, who does not have a tracheotomy tube, preoperative administration of dexamethasone, 0.5 mg/kg up to a maximum of 20 mg, is a prudent precaution.

Rigid endoscopy remains the 'gold standard' for paediatric airway evaluation, and this evaluation should

begin with an assessment of the supralaryngeal airway. The possible presence of retrognathia and any associated glossoptosis or difficulty of laryngeal exposure should be initially assessed, as should tonsillar hypertrophy or evidence of pharyngeal scarring. The supraglottic larynx should be carefully assessed for scarring, laryngomalacia, short aryepiglottic folds and arytenoid prolapse. The glottis should be evaluated for scarring, anterior glottic webbing and posterior glottic stenosis, and care should be taken to exclude the presence of a posterior laryngeal cleft. If vocal motion is clearly seen, it can be assumed that neither true vocal cord is paralyzed. If, however, movement is not observed, nasopharyngoscopy with the patient awake should be performed. The subglottis should be evaluated, and any stenosis or scarring noted. If stenosis is present, its severity, length, position and physical characteristics should be noted. It may be characterized as soft or firm, as concentric or with lateral shelving, and with mucosa appearing either quiescent or actively inflamed.

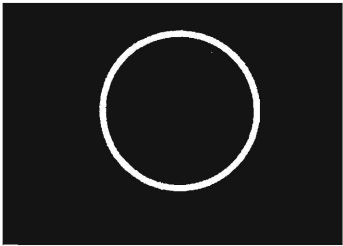

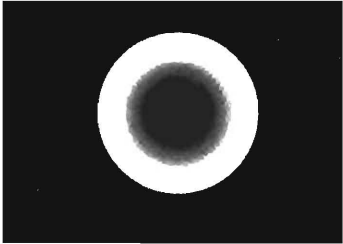

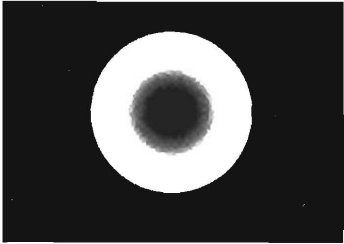

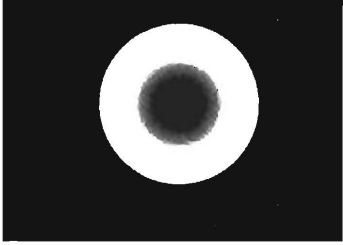

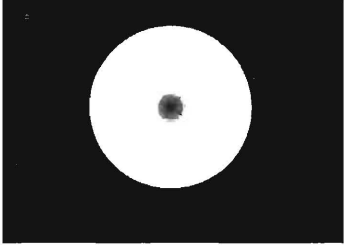

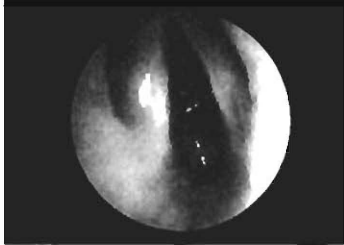

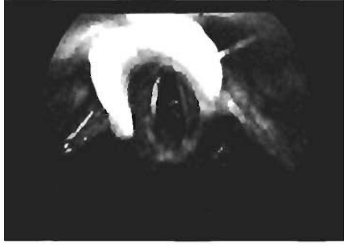

If there is a sufficient lumen to allow passage of the endoscope, the trachea is next assessed. Hopkins rod endoscopes with an outer diameter as small as 1.9 mm are available, and can negotiate most grade III subglottic stenoses. An assessment is made of the upper trachea, including the tracheotomy stoma site, looking for suprastomal collapse or the presence of a suprastomal granuloma. Assessment is also made of possible tracheomalacia and vascular compression of the airway. Although complete tracheal rings are rare, their possible presence should be evaluated cautiously, so as not to induce oedema within an already compromised segment of airway. The carina and mainstem bronchi are also evaluated.

If subglottic stenosis has been identified, the area of stenosis should be graded according to the Myer–Cotton classification¹ (see Table 89.1). This is best carried out utilizing endotracheal tubes, with a small tube being placed initially. If this tube leaks at less than 20 cm of water pressure through the subglottis, the next larger size is placed. It should be noted that the Myer–Cotton grading system is not designed to address supraglottic, glottic or tracheal stenosis.

ANAESTHETIC TECHNIQUE DURING BRONCHOSCOPY

A collaborative relationship with the anaesthetist is essential in deciding upon the specific anaesthetic technique to be used when performing rigid endoscopy. Possible options include spontaneous ventilation, assisted ventilation, jet ventilation and apnoea with intermittent bag and mask ventilation. Spontaneous ventilation offers the best dynamic assessment of the airway and is thus recommended. Endoscopy may be performed with the laryngoscope introduced into the airway and suspended in position. This frees both the surgeon's hands for introduction of a telescope and instruments as required. Some surgeons prefer to expose the larynx with an

Table 89.1 The Myer–Cotton classification.

Grade	From	To	Examples
I	 No obstruction	 50% obstruction	
II	 51% obstruction	 70% obstruction	
III	 71% obstruction	 99% obstruction	
IV	No detectable lumen		

Redrawn from Ref. 1, with permission.

anaesthetic laryngoscope blade held in one hand and use the other hand to introduce a telescope. Endoscopy may also be performed with a ventilating bronchoscope or a Hopkins rod telescope, keeping in mind that the technique itself is not as important as the information gained. We prefer to use the Hopkins rod telescope, exposing the larynx with a straight anaesthetic laryngoscope blade. The child spontaneously ventilates a mixture of sevoflurane and oxygen through an endotracheal tube placed in the oropharynx, and with additional intravenous anesthesia provided by propofol bolus.

FLEXIBLE BRONCHOSCOPY

In selected children, flexible bronchoscopy may complement rigid bronchoscopy and both may occasionally be

required to evaluate a child’s airway adequately. Also, in many instances, these techniques can be used interchangeably. In some cases, however, each technique offers clear advantages. Rigid bronchoscopy provides a superior assessment of the larynx, especially the posterior glottic area. Flexible bronchoscopy is often extremely valuable in assessing a larynx that is difficult to access with rigid instrumentation and may provide valuable information about airway dynamics, such as the degree of pharyngeal collapse, glossoptosis and the presence of laryngomalacia, tracheomalacia or bronchomalacia. Flexible bronchoscopy also permits evaluation beyond the eighth generation of bronchi in older children and allows specific lavage of bronchial subsegments, which may provide information about silent aspiration if lipid-laden macrophages are found.

Gastrointestinal evaluation

OESOPHAGOGASTRODUODENOSCOPY, OESOPHAGEAL BIOPSY AND pH PROBE

In selected cases, particularly in patients with complex underlying medical conditions or in those who have failed previous airway reconstruction, oesophagogastroduodenoscopy may be beneficial in the assessment of a child prior to airway reconstruction. Oesophagogastroduodenoscopy can provide information about oesophagitis, gastritis and the status of the lower oesophageal sphincter, especially in regard to whether a previous fundoplication is still functional.

Preoperative evaluation of gastro-oesophageal reflux with dual probe pH monitoring and/or oesophageal biopsy is advisable, and should be mandatory in a child with an active larynx or recalcitrant airway stenosis following previous reconstruction.² [**/*] Oesophageal biopsy will also provide information about oesophagitis, including the possibility of eosinophilic oesophagitis, and is currently the only method of diagnosing and monitoring this condition.

Placement of a pH probe may be done at the time of oesophagogastroduodenoscopy, at the time of bronchoscopic evaluation or may be performed as an elective procedure unrelated to endoscopic evaluation. Patients should be off antireflux medication for at least one week prior to pH probe placement. A dual pH probe with the upper port lying in the postcardiac region is desirable. While normal paediatric values for the upper port do not exist, positive readings should be viewed with suspicion. The recently developed impedance probe not only measures acid, but can also provide an indication of the volume of a reflux bolus and the height in the oesophagus to which it progresses. Impedance technology also allows evaluation of nonacid reflux. This enables a child to remain on antireflux medication prior to evaluation.³ [**/*] While this technology is promising, no paediatric norms yet exist, and interpretation of the vast amount of data generated by an impedance probe is both time-consuming and challenging.

Evaluation of aspiration

Paediatric airway reconstruction runs the inherent risk of turning a child with laryngeal stenosis into a chronic aspirator. While this risk cannot always be accurately evaluated preoperatively, in most cases a thorough evaluation provides ample warning signs. Recurrent pneumonia and an insidious drop in a child's baseline oxygen saturation are highly suggestive of chronic aspiration. A history of previous aspiration or current aspiration is extremely important. In a child who is tracheotomy dependent, copious tracheotomy secretions or secretions stained by food material indicate chronic

aspiration. This is more difficult to evaluate in a child who is entirely gastrostomy (G-tube) fed. A simple solution is intermittently to place a drop of green food dye on the child's tongue and evaluate whether green-stained secretions are subsequently suctioned from the tracheotomy tube. Alternatively, a radio nucleotide spit study may be performed; a drop of radioactive material is placed on the tongue and its passage is monitored to either the stomach or lung fields. In a child suspected of aspirating, a bronchoalveolar lavage, which can identify lipid-laden macrophages, may be useful. This does not, however, provide useful information in a child who is wholly G-tube fed. Children with grade IV subglottic stenosis, in whom aspiration is not possible prior to laryngotracheal reconstruction, present a particular challenge. In these children, preoperative evaluation to assess the relative risk of aspiration is strongly advocated.

A barium swallow or video swallow study may provide information not only on the presence of aspiration, but also on what substances are most likely to be aspirated. Thin fluids are more likely to be aspirated than purees or solids.

A functional endoscopic evaluation of swallowing, whereby the larynx is visualized with a nasopharyngoscope while a child swallows food or drink, can provide valuable information about the relevant risk of aspiration and the mechanism of aspiration as well as the presence or absence of normal laryngeal sensation.

Having knowledge of the possibility of postoperative aspiration allows for appropriate preoperative counselling and management to minimize this risk. Innately, there are three things that may be aspirated, namely food and drink presented by mouth, saliva and gastric reflux. The respective risk of each can be minimized by conversion to G-tube feeding, reducing saliva production through a 'drool' procedure, and performing a fundoplication. Most children and families presented with the choice of a gastrostomy tube or a tracheotomy tube will choose the former.

Sleep evaluation

A formal sleep evaluation may be a useful method to evaluate a child's respiratory efforts and oxygen needs, whether or not a tracheotomy is in place. The primary aim of laryngotracheal reconstruction is decannulation, and this operative procedure is rarely warranted if decannulation cannot be achieved. In children with tracheotomy dependency, it is important to evaluate whether surgical correction of laryngeal stenosis will permit decannulation. In children with significant lung disease, particularly bronchopulmonary dysplasia or in those who are dependent on a ventilator or CPAP, decannulation may be imprudent. Similarly, children with progressive neuromuscular disorders, diaphragmatic weakness or central hyperventilation syndrome, may not

be candidates for decannulation. If results of a sleep evaluation indicate pulmonary compromise that precludes decannulation, laryngeal reconstruction may be futile.

Voice evaluation

Voice evaluation in children with laryngeal stenosis, tracheotomy dependency or following laryngotracheal reconstruction is in its infancy and is poorly understood. It is clear, however, that laryngeal reconstruction can have a negative impact on the voice, particularly in children requiring supraglottic or glottic surgery and in those in whom a laryngofissure is required to reconstruct the airway. What is unclear is which underlying pathologies and reconstructive procedures place the voice at greatest risk, and also the extent to which a voice anomaly relates to the initial aetiology of the laryngotracheal stenosis.

Children have a tremendous drive to communicate, which often compensates for severe anatomic dysfunction. Some children will retain a surprisingly good-quality voice, even with a grade III subglottic stenosis. However, children with a grade IV subglottic stenosis are aphonic unless they have learned oesophageal speech techniques. In these children, laryngotracheal reconstruction may be extremely beneficial in terms of regaining voice, even if decannulation is not achieved.

CONSIDERATIONS PRIOR TO LARYNGEAL RECONSTRUCTION

Surgical intervention for laryngeal stenosis is not always warranted, and the decision as to whether or not to perform such surgery is generally predicated by the overall health status of the child rather than by the stenosis itself. In a child with a high risk for aspiration or with certain craniofacial anomalies, surgical reconstruction may be inappropriate in that the laryngeal stenosis may actually protect the lungs from aspiration. In some children, ongoing aspiration may lead to a consideration of laryngotracheal separation rather than laryngeal reconstruction. Similarly, in children with other significant medical conditions, such as those requiring CPAP, bilevel positive airway pressure (BiPAP) or ventilator support, reconstruction is unwise. While not universally accepted or rigorously proven, most experts in paediatric laryngotracheal reconstruction believe that gastro-oesophageal reflux disease is both a cofactor for the development of subglottic stenosis and a negative influence on the outcome of operative reconstruction. Oxacillin or methicillin-resistant *Staphylococcus aureus* (MRSA) screening prior to open airway surgery is also recommended, as postoperative infection may greatly compromise the surgical repair. Although a child with a progressive neuromuscular disorder may be considered for laryngotracheal reconstruction to improve vocal function, this seldom enables long-term decannulation.

In some children, a period of observation prior to considering surgical intervention is the best course of action. This strategy is most appropriate in a child with an active or inflamed larynx that is not amenable to medical intervention. An active larynx is generally related to gastro-oesophageal reflux disease or eosinophilic oesophagitis and is, therefore, potentially amenable to such intervention. In children in whom the aetiology of an active larynx is unknown, laryngeal reconstruction is unwise until the laryngeal inflammation has improved. This often occurs spontaneously within a one- to two-year period. A waiting period is also advisable in a child who has recalcitrant stenosis after a recent airway reconstruction, or in a child whose larynx is healing from laryngeal trauma. While only a guideline, a six-month 'cooling off' period is often advisable in such children.

Although weight is a less important factor than the overall health status of a child and the child's laryngeal disease, it is a frequently used criterion for postponement of airway reconstruction. While laryngotracheal reconstruction can be effectively performed in children less than 3 kg if other criteria permit, a 10 kg guideline is most commonly used. Nevertheless, airway reconstruction of a larger child is technically much easier to perform.

The child with complex medical problems

Historically, children presenting for airway reconstruction were otherwise healthy children with a stenosed larynx. Increasingly, however, children presenting for airway reconstruction have multifaceted complex medical problems, most commonly related to either extreme prematurity or syndromic conditions (see Chapter 64, ENT input for children with special needs). In such children, an interdisciplinary team approach is advisable for adequate assessment both before and after planned reconstruction. The most important decision to be made is whether it is advisable to even attempt reconstruction. If so, consideration must be given to other interventions indicated prior to proceeding with laryngeal reconstruction. In a child with reflux disease, a fundoplication may be required. In a child with aspiration, a 'drool' procedure may be required. It is prudent to have most of these children undergo additional evaluation by paediatric subspecialists in pulmonology, gastroenterology, medical genetics and neurology.

THERAPY

Medical therapy

When the larynx is stable and quiescent there is no role for medical therapy. In the inflamed or active larynx,

however, medical therapy plays an important role in alleviating laryngeal inflammation which, in turn, enhances the potential for a successful operative outcome. In children with subglottic stenosis, medical therapy alone occasionally obviates the need for laryngeal reconstruction by providing sufficient improvement to permit decannulation.

Medical therapy for an inflamed larynx revolves around treatment of gastro-oesophageal reflux disease or eosinophilic oesophagitis. If reflux is diagnosed or even suspected, then a low threshold for treatment with H₂ antagonists or proton pump inhibitors is recommended. In children with recalcitrant acidic reflux or significant nonacid reflux, consideration should be given to performing fundoplication.

A recent observation has been the correlation between eosinophilic oesophagitis, laryngeal inflammation and a poor outcome following laryngotracheal reconstruction.⁴ [**/*] Eosinophilic oesophagitis has a characteristic appearance on oesophagogastroduodenoscopy, with oesophageal furrows often having microscopic white plaques noted. However, the definitive diagnosis is made on biopsy, with greater than 20 eosinophils per high-power field being noted. In children with eosinophilic oesophagitis, evaluation for underlying food allergies is indicated. In children in whom a food allergy is not proven, treatment with oral fluticasone is suggested. An initial dosing regimen of 440 µg, sprayed on the tongue twice a day and swallowed, is usually efficacious. Follow-up oesophagoscopy with further biopsies to confirm resolution of disease is suggested prior to undertaking laryngeal reconstruction, which is usually delayed for six months.

Tracheotomy

In a child with an unsafe or unstable airway in whom laryngotracheal reconstruction is not immediately advisable, temporary placement of the tracheotomy tube is advisable to secure an adequate airway until laryngeal reconstruction can be performed. Placement of a tracheotomy should be performed with a view to the subsequent laryngeal reconstruction that may be required. A high tracheotomy close to the cricoid increases the risk of exacerbation of stenosis, but may make subsequent cricotracheal resection (CTR) simpler as a shorter segment of airway can then be resected. Tracheotomy through the second to fourth tracheal rings is still recommended.

Although a tracheotomy provides a safer airway in a child with laryngotracheal stenosis, the airway is by no means completely safe. Tracheotomy-related deaths continue to occur in children who could otherwise anticipate good long-term quality of life, and the greater the degree of obstruction, the greater the risk. A tracheotomy is a marked compromise on both a child's and a family's quality of life and emotional health.

Laryngeal reconstruction

Laryngeal and upper tracheal reconstruction may be challenging and no single operation can adequately address all types of laryngeal stenosis. It is thus prudent to evaluate each child on an individual basis. In some patients, the most appropriate reconstruction technique may not become fully clear until the airway has been opened and the pathology directly inspected. The mainstay of laryngotracheal reconstruction is expansion cartilage grafting (Figure 89.1). In the subglottis an alternative to this approach is resection and reanastomosis. Stenosis involving the supraglottis and anterior glottis is amenable to laryngoplasty without cartilage grafting.

GRAFTING MATERIALS

Costal cartilage is the most widely used grafting material, with excellent results noted on prolonged follow-up.^{5,6} [**] It is readily available, robust and easily shaped and carved. Moreover, it is possible to harvest more than one graft through the same incision. The usual donor site is the right fifth or sixth rib, with the incision being placed in the anticipated breast crease in girls for cosmetic reasons. The harvested graft should include the perichondrium on the lateral aspect of the graft, while leaving the inner perichondrial layer intact at the donor site to allow the potential for some cartilage regeneration. Once the graft is harvested, filling the wound with saline and performing a Valsalva manoeuvre will ensure that a breach of the pleura has not occurred. When the graft is carved to the desired shape, the perichondrium should face the lumen of the airway; lateral flanges will prevent prolapse of the graft into the airway.

When only a small graft is required, thyroid ala is a useful material. This is usually taken from the upper aspect of the thyroid cartilage on one side, at least 1 mm above true vocal cord level. Thyroid ala has the advantage of being quickly and easily harvested from within the surgical field. However, only a limited amount of grafting material is available, and it is not amenable to being carved with flanges.

Auricular cartilage is also useful, in particular for the management of suprastomal collapse as part of a single-stage procedure. It is easily harvested and reasonably abundant. It makes an ideal cap or overlay graft, particularly over a stoma site, but is comparatively weak and not appropriate for insertion between the cut edges of the cricoid. In both adults and older children there is no cosmetic donor site deformity, but in children under one year of age it is common to have some residual asymmetry of the ears.

Other grafting materials include buccal mucosa, septal cartilage and a pedicled hyoid bone interposition graft. The results utilizing these grafting materials in children have been disappointing. Another described technique is

Figure 89.1 Expansion cartilage grafting.

the use of a clavicular periosteal graft, with its vascularity maintained by swinging the graft up on a pedicle of sternocleidomastoid muscle. This is a useful graft in older children in whom there is a significant deficit of tracheal cartilage, as after several months the graft will start to ossify, thereby providing support to the airway. Unfortunately, in prepubescent children the graft seems less amenable to ossification, leaving the airway malacic.

STENTS

Not all laryngotracheal reconstruction techniques require stent placement. It may not be required in an anterior flanged graft for moderate subglottic stenosis, however, it is advisable in virtually all other circumstances. Stenting maintains a lumen and prevents graft prolapse during postoperative healing, and may remain in place for days

to months. Longer-term stents are advisable when the laryngeal repair is unstable (e.g. when a posterior cricoid split has been performed in an older child without placement of a cartilage graft), or in a recalcitrant larynx that has failed previous reconstruction. In patients in whom graft survival is threatened, such as diabetic patients and patients on continuous steroids, long-term stenting without cartilage grafts is advisable. The most commonly used stent is the Aboulker Teflon suprastomal stent (**Figure 89.2**). It is critical that the lower end of this stent does not overlap the tracheotomy site, as this creates the risk of being unable to reinsert a tracheotomy tube during a tracheotomy change. In addition, in some children the cut lower end of the stent is prone to inciting granulation tissue above the stoma site and eventually forms fibrosis and scarring. Suprastomal stents should thus, ideally, be removed within six weeks, as any granulation tissue that has formed during this time will spontaneously resolve.

An alternative to a rigid Teflon suprastomal stent is a softer silicone stent (e.g. the upper limb of a tracheal T-tube). The cut end of this stent is sewn shut and placed in the supraglottis, while its machined smooth end is placed distally to overlap the tracheotomy site slightly. These stents are soft and deformable and do not interfere with placement of the tracheotomy tube. They tend to incite less granulation tissue at the distal end of the stent, and there is less dead space between the distal end of the stent and the tracheotomy tube in which scarring can occur. Unlike the rigid Teflon stents, these soft silastic suprastomal stents may remain in place for longer than

Figure 89.2 Aboulker Teflon suprastomal stent.

six weeks. The proximal end of a suprastomal stent should lie at the level of the false vocal cords. There will be a corresponding restriction of speech, as they permit only limited air passage.

For longer-term stenting, tracheal T-tubes are recommended. Although T-tubes with an outer diameter of 5 mm are commercially available, because of the risk of crusting and obstruction we do not routinely place T-tubes with an outer diameter of less than 8 mm. An 8-mm tube may be placed in a child as young as four years of age. Following laryngeal reconstruction, the upper end of a T-tube is generally passed through the vocal cords. Aspiration is, therefore, a significant risk and is expected for two weeks following stent placement. A supraglottic swallow technique is readily achieved by most children, minimizing the risk of aspiration. Unlike tracheotomy tubes, T-tubes cannot be easily changed. Meticulous T-tube care is thus essential.

SINGLE-STAGE RECONSTRUCTION

In children in whom a stenting period of less than two weeks is anticipated, an option to be considered is intubation, with the endotracheal tube acting as the stent.⁷ [**] Intubation for greater than two weeks, however, risks redevelopment of posterior glottic stenosis or subglottic stenosis. For straightforward airway reconstruction, extubation may occur within a few days of the operation or, occasionally, even at the end of the reconstructive procedure. Although the optimal duration of intubation is not clearly defined, there has been a trend towards briefer periods of intubation following laryngotracheal reconstruction. Most children can be extubated within two to seven days of a CTR or an anterior costal cartilage graft. Those with anterior/posterior cartilage grafts are usually intubated for 7–14 days. The older the child, the more forgiving the airway and the briefer the period of intubation required. For more complex airway surgery, a prolonged period of intubation is required.

A prerequisite for single-stage laryngotracheal reconstruction is an excellent intensive care unit (ICU) in which staff are familiar with the management of airway patients. It is undesirable for a child to have an unplanned self-extubation, and security of the nasotracheal tube is paramount. Therefore, in younger children, the use of arm restraints and sedation is usually required. Most children younger than age three require sedation, and children who have been previously intubated for long periods may require heavy sedation. Paralysis is undesirable as in the event of accidental decannulation the child is unable to maintain an airway and reintubation must be emergent. Since any child undergoing a single-stage procedure risks the need for reintubation, single-stage procedures should not be performed on children who are difficult to intubate. In the sedated child, commonly encountered problems include lung atelectasis, fluid

overload from heavy sedation, pneumonia and narcotic withdrawal following extubation.

In children older than age three with no major cognitive problems, sedation may not be required. Some of these intubated children may be able to ambulate, eat and visit the playroom. A fully awake child does not require ventilatory support and is less likely to have pulmonary complications from the intubation.

The day prior to extubation, returning to the theatre to inspect the airway and downsize the tracheotomy tube is advisable. If the airway appears adequate to support extubation, a dose of dexamethasone, 0.5 mg/kg, is administered the night before extubation, and the patient is extubated while fully awake. Owing to the risk of laryngeal oedema, the patient should be closely observed on the ICU for the next 24 hours; oedema generally resolves within this period of time. In the event of airway distress following extubation, management options include the administration of racemic adrenaline, further steroids, helium/oxygen administration or even the use of CPAP or BiPAP. If the airway is still not adequate the child may need to be reintubated. If so, a further trial of extubation should be performed a few days later. If this is again unsuccessful a decision is required as to whether to proceed to a third trial of extubation or to proceed with tracheotomy. If a tracheotomy is required, the stoma should ideally be placed low in the neck, below the graft site. Glottic oedema and granulation from endotracheal tube irritation are often the cause of failure during a single-stage procedure, rather than the reconstructed site itself. In such cases, the tracheotomy tube may be removed once the oedema has settled, usually within a few weeks.

The ideal patient for consideration of a single-stage procedure is one in whom a reasonably simple procedure with a stable larynx is anticipated. This single-stage approach is preferable in children in whom a tracheotomy tube has induced suprastomal collapse. Poor candidates for single-stage reconstruction include children with poor pulmonary function, those who are difficult to intubate, those with recalcitrant airway disease who have failed previous reconstruction, and those with complex disease involving multiple levels of obstruction.

Supraglottic stenosis

Supraglottic stenosis is rare, difficult to treat, and is frequently associated with supraglottic collapse. While severe supraglottic stenosis may present with stridor, the primary complaint is more commonly obstructed breathing during sleep. Therefore, a sleep study may be extremely useful in the nontracheotomized patient or in the patient in whom the tracheotomy can be capped, even if for a brief period. The underlying aetiology is often traumatic, due to severe direct airway trauma or airway burns, or is of iatrogenic origin. Supraglottic stenosis with

associated collapse is a feature of the airway that has undergone numerous laryngeal reconstructions. Visualization of the supraglottic larynx in cases of supraglottic stenosis and collapse may be misleading. Rigid endoscopic evaluation with the larynx suspended by a laryngoscope may distort the appearance of the larynx, providing false reassurance about the supraglottic airway. Flexible endoscopic evaluation with the patient spontaneously ventilating allows for superior evaluation of the airway dynamics. Nevertheless, what is observed may be deceiving. A larynx that looks extremely compromised in an anaesthetized patient may function quite adequately in the nonanaesthetized state.

In children with mild-to-moderate supraglottic stenosis and collapse, nocturnal CPAP may be very beneficial. The most common patterns of supraglottic compromise are arytenoid prolapse and epiglottic petiole prolapse. Arytenoid prolapse is a dynamic instability of the arytenoid, either unilateral or bilateral. It is characterized by its anterior displacement during inspiration, which may cause significant airway obstruction. This problem most commonly follows previous CTR or previous laryngotracheal reconstruction involving division of the posterior cricoid plate. In CTR, the pathogenesis of arytenoid prolapse may be attributed to division of the lateral cricoarytenoid muscle. In laryngotracheal resection, the pathogenesis of arytenoid prolapse may be attributed to either direct damage to the posterior cricoarytenoid ligament or lateral distraction of the posterior plate of the cricoid.

Arytenoid prolapse is usually managed endoscopically, using a laser to perform a partial arytenoidectomy. The preferred technique is to raise a mucosal flap and debulk the prolapsing cartilage of the arytenoid without damaging the mucosal 'diamond' of the laryngeal inlet. Injudicious use of the laser in the laryngeal inlet predisposes patients to scar formation, fibrosis and narrowing of the supraglottic airway. This, in turn, may induce superimposed supraglottic collapse due to the Bernoulli effect.

Epiglottic petiole prolapse

This presents as a compromised laryngeal inlet owing to the base of the epiglottis (the 'petiole', from the term used to describe the footstalk of a leaf, i.e. the part which connects the blade to the stem) obscuring the anterior true vocal folds and foreshortening the anterior/posterior diameter of the laryngeal inlet. This problem is most commonly seen in children who have had repeated previous laryngofissure, and is a consequence of damage to the thyroepiglottic ligament, where it inserts into the thyroid cartilage just above the anterior commissure. Epiglottic petiole prolapse is rare, and challenging to treat. Injudicious use of a laser in the endolarynx tends to exacerbate the problem, with further scarring narrowing

the laryngeal inlet. Suspension of the epiglottic base to the hyoid bone provides some benefit, but is technically challenging and causes the patient significant pain on swallowing for several weeks postoperatively.

Our current management of this challenging problem is to perform a complete laryngofissure and reposition the epiglottic petiole back up to the inner surface of the thyroid ala. The laryngofissure is then closed over a T-tube, which is left in position as a translaryngeal stent for at least six months. These patients have significant problems with aspiration for several weeks postoperatively.

Acquired anterior glottic webs

Anterior glottic webs are most commonly congenital in origin, and are usually associated with a subglottic extension of the web resulting in coexistent subglottic stenosis (see Chapter 88, Congenital disorders of the larynx, trachea and bronchi). Acquired anterior glottic webs are less common and are post-traumatic in origin. There are two common aetiologies: anterior neck trauma, often associated with a fractured larynx; and iatrogenic damage, often associated with injudicious use of a laser at the anterior commissure while managing laryngeal papillomatosis. It is rare for prolonged intubation to induce anterior glottic stenosis unless there is also associated subglottic stenosis.

The management of acquired anterior glottic stenosis differs significantly from the management of the congenital anterior glottic web. The latter has normal mucosa within the remaining glottic inlet, and during reconstruction there may be sufficient mobility of the mucosal layer to reconstruct the anterior commissure without requiring the use of a laryngeal keel. In contrast, acquired anterior glottic stenosis is, by definition, associated with fibrosis and scarring. As such, during reconstruction, following laryngofissure, the mucosa is fibrotic and not amenable to reconstruction of the anterior commissure. Therefore, reconstruction with placement of a laryngeal keel is mandatory while the raw surfaces on either side of the laryngofissure remucosalize.

The usual technique for repair of an acquired anterior glottic web is an open approach with complete laryngofissure, and it is recommended that this is performed with endoscopic guidance. With the laryngofissure complete, the demucosalized raw scar of the anterior vocal folds are noted and, in some cases, there may be enough mucosal mobility to place a pexing suture from the cut edge of the mucosa on either side toward the thyroid ala. Unlike repair of congenital anterior glottic webs, it is unusual to be able to pex the mucosal edge up to the anterior commissure, hence the need for a laryngeal keel. An appropriate size laryngeal keel, such as the Montgomery KeelTM, is then selected and trimmed appropriately. The vertical limb of the keel should not impinge into the posterior commissure. The vertical height of the keel

should separate the raw surfaces of the laryngofissure. The upper limit of the keel should not be so high as to disrupt the insertion of the epiglottic petiole.

The keel is then sewn into place and the laryngofissure closed. This procedure is normally performed as a two-stage procedure, although a single-stage procedure may be performed with the patient intubated and with the endotracheal tube lying on one side of the vertical limb of the keel. In some children there is an associated component of subglottic stenosis, and a decision should be made at this point as to whether the cricoid can be closed adequately over an age-appropriate endotracheal tube. If this is possible, the lower end of the keel should not extend beyond the cricothyroid membrane. If it is not possible, an anterior cartilage graft is placed in the anterior cricoid, distal to the keel.

The keel is removed through an open approach between ten days and four weeks postoperatively. The resultant midline deficit in the thyroid ala is then closed with laterally placed mattress sutures, as the cartilage edges of the laryngofissure are friable and easily damaged if sutures pull out. For this reason, antibiotic coverage and antireflux measures are advised during the period that the keel is in place, and for an additional few days after keel removal.

Endoscopic placement of the laryngeal keel is also a consideration, although this is technically more challenging and may require more specialized equipment. This technique is best suited for adults and older children.

Posterior glottic stenosis

Posterior glottic stenosis is frequently misdiagnosed and often confused with bilateral true vocal cord paralysis. It may exist as an isolated entity or in combination with subglottic stenosis. The most frequent aetiology of this condition is prolonged intubation, with the older child being at greater risk than the neonate. The posterior glottis is also susceptible to damage from thermal injury caused by inhalational or airway fires, or to iatrogenic damage from use of the laser in the posterior commissure. Occasionally, posterior glottic stenosis may be a result of direct laryngeal trauma.

If not already tracheotomy dependent, patients present with stridor and exertional dyspnoea. Normal vocal function is usually preserved and, in this regard, presenting symptomatology is extremely similar to that seen in bilateral vocal cord paralysis. Definitive diagnosis requires assessment with rigid bronchoscopy, which confirms the presence of posterior glottic scarring, as a rigid telescope provides excellent visualization of the posterior glottis. Posterior glottic stenosis can, however, be misdiagnosed on bronchoscopy if the telescope is passed directly through the vocal folds to evaluate the subglottis without proactive inspection of the posterior glottis. Bronchoscopic evaluation should also include

assessment of the subglottis, which is frequently involved with scarring. An assessment of arytenoid mobility is required as cricoarytenoid joint fixation is an occasional co-pathology. Formal sizing of the airway utilizing endotracheal tubes may be misleading. Posterior glottic stenosis may limit the size of the endotracheal tube that may be inserted. In some cases, however, the vocal folds easily bow laterally to accommodate an age-appropriate endotracheal tube despite still being tethered posteriorly, compromising the airway. It should again be emphasized that the Myer–Cotton grading system is only truly applicable to subglottic stenosis.

While flexible bronchoscopy provides a poor view of the posterior glottis and is an inadequate method of diagnosing posterior glottic stenosis, awake flexible nasopharyngoscopy may be extremely useful in determining whether vocal fold function is intact. The usual finding is that the vocal folds are mobile but tethered and unable to abduct. It is rare for bilateral vocal cord paralysis and posterior glottic stenosis to coexist.

The differential diagnosis for posterior glottic stenosis commonly includes subglottic stenosis (which frequently may also be present), an interarytenoid scar band and cricoarytenoid joint fixation. In children referred for the management of posterior glottic stenosis, it is rare to find vocal cord paralysis. By contrast, children referred for the management of bilateral vocal cord paralysis may, in fact, have posterior glottic stenosis tethering the vocal cords and masquerading as vocal cord paralysis.

Placement of a posterior costal chondral graft is the mainstay of management and is a highly effective way of achieving an adequate glottic airway.^{8,9} [**] This procedure is best performed through an anterior approach, traditionally through a complete laryngofissure. This approach allows excellent exposure of the posterior glottis and direct visualization of the posterior glottic scar band. The posterior glottis is then infiltrated with 1 percent Xylocaine with adrenaline. The needle is guided through the posterior plate of the cricoid in the midline until it can be felt to pop through into the space between the posterior cricoid and the oesophagus. A further small amount of Xylocaine and adrenaline may then be injected in two or three positions down the cricoid. This has the advantage of not only providing haemostasis in the postcricoid region, but also of providing an additional buffer zone between the posterior cricoid plate and the oesophagus. The posterior cricoid can then be split vertically for its entire length, ensuring that the incision is kept completely in the midline. It is important that the interarytenoid scar band is completely divided. The incision may be continued superiorly through the interarytenoid muscles (which are frequently fibrosed) up to the level of the interarytenoid mucosa itself. Care must be taken not to inadvertently form a posterior laryngeal cleft. Following the posterior split, the cricoid should be easily distracted laterally. A costal cartilage graft is then harvested and carved so that its height is

approximately the height of the cricoid split and its depth allows the graft perichondrium to lie reasonably flush with the cut mucosa of the posterior cricoid. The graft may be sewn in place with 4.0 MonocrylTM sutures on a P2 needle. An alternative approach is to form a flanged graft that can be snapped into place and stabilized with a small amount of fibrin tissue glue. With the posterior graft in place, the laryngofissure is then closed over an age-appropriate endotracheal tube. If the cricoid does not easily close anteriorly, a further segment of costal cartilage is used as an anterior cricoid graft. A posterior graft rarely needs to be more than 6 mm wide as the primary aim of surgery is to incise the scar tissue and hold the raw edges apart while healing takes place. A graft surpassing this width carries an increased risk of aspiration.

It is possible to perform this procedure without performing a complete laryngofissure. If the anterior airway incision is carried up to the true vocal cords but not through them, there is usually sufficient access to perform a safe posterior cricoid split and allow insertion of a flanged graft. Such a graft is required as there is not adequate access to comfortably place sutures with this technique. This technique is more difficult to perform in small children.

Posterior cricoid grafting may be performed as a single- or two-stage procedure. Other variations of open reconstruction include scar excision alone, buccal mucosal grafting and a posterior cricoid split without graft placement. However, a posterior split without a graft normally requires a considerable period of stenting before full stability is achieved. This technique is more efficacious in younger children.

Endoscopic techniques may also be efficacious although, in general, are not as reliable as the open approach. A laser posterior cordotomy with or without partial arytenoidectomy is effective, however, there is a significant chance of restenosis. In order to prevent restenosis, the use of mitomycin C is a consideration, as well as placement of a temporary transglottic stent. Other described techniques for the endoscopic management of posterior glottic stenosis include mucosal advancement flaps, microtrapdoor flaps, vocal cord lateralization and botulinus toxin (Botox) injections.

Whether reconstruction is open or endoscopic, there is a restenosis rate of between 10 and 20 percent. This rate is higher in children who have had thermal injury to the posterior glottic stenosis. If a child has failed an endoscopic procedure, then open reconstruction is appropriate. Conversely, if a child has failed an open procedure, endoscopic management may be appropriate. In a very recalcitrant airway it is possible to place a second posterior costal cartilage graft if required.

Interarytenoid adhesion

Interarytenoid adhesion is a distinct variant of posterior glottic stenosis, with presentation similar to this

condition or to bilateral true vocal cord paralysis. An interarytenoid adhesion results from prolonged intubation, when tongues of granulation tissue lying anterior to the endotracheal tube in the region of the vocal process unite in the midline to form a fibrous scar band. While this usually progresses to form posterior glottic stenosis, mucosal sparing of the posterior commissure sometimes occurs, resulting in the formation of an interarytenoid scar band. Endoscopic evaluation confirms a small posterior commissure air passage and a larger anterior glottic airway passage. However, there may be a marked limitation to the size of endotracheal tube that can be used for intubation if there is not a tracheotomy tube already present. Endoscopic resolution of this problem is simple and effective. In most cases, microlaryngeal scissors are used to excise the scar band, with immediate resolution of symptoms. In some children this problem may coexist with either subglottic stenosis or posterior glottic stenosis.

Subglottic reconstruction

REPAIR TECHNIQUES

Anterior cricoid split

In the neonate who has failed extubation the anterior cricoid split procedure is an alternative to tracheotomy (Figure 89.3). The criteria for anterior cricoid split are well described and are:¹⁰

- failed extubation on at least two occasions;
- weight >1500 g;
- extubation failure secondary to laryngeal pathology;

- no assisted ventilation for ten days before evaluation;
- supplemental O₂ requirement <35 percent;
- no congestive heart failure for one month prior to evaluation;
- no acute upper or lower respiratory tract infection at the time of evaluation;
- no antihypertensive medication for ten days before evaluation.

The procedure involves an anterior incision of the trachea from the second tracheal ring, up through the cricoid and into the lower third of the thyroid ala, just below the insertion of the anterior commissure. The child is then left intubated for ten days, with the neck wound left at least partly open to minimize the risk of subcutaneous air build-up. A thyroid alar interposition graft is a modification that permits earlier extubation.

Laryngotracheal reconstruction: anterior cartilage graft

Mild-to-moderate subglottic stenosis is well managed with costal cartilage grafting to the anterior cricoid (Figure 89.1).¹¹ The anterior airway is split from the tracheotomy site to the lower aspect of the thyroid cartilage. An age-appropriate sized endotracheal tube or supraglottic stent is then inserted, and a measurement taken of the size of graft needed to comfortably close the deficit in the anterior airway. A costal cartilage graft is then harvested and carved to allow a boat-shaped and perichondrium-lined insert to distract the anterior cricoid. An outer flange prevents graft prolapse into the airway. This technique is also useful for managing supraglottic collapse or narrowing of the upper trachea.

Figure 89.3 The anterior cricoid split procedure.

Laryngotracheal reconstruction: posterior cartilage graft

Costal cartilage grafting of the posterior cricoid for subglottic stenosis may be performed in an identical fashion as for posterior glottic stenosis. If the anterior cricoid can then close comfortably over an appropriate sized endotracheal tube or stent, the additional anterior grafting is not required.

Laryngotracheal reconstruction: anterior and posterior cartilage grafts

If the anterior cricoid cannot comfortably close over an appropriately sized endotracheal tube or stent, then an

additional anterior graft is required, as previously described. This is necessary for most grade III and all grade IV stenoses.

Cricotracheal resection

Cricotracheal resection has an increasing role in the management of subglottic stenosis. This procedure requires the removal of the subglottic scar tissue, with the anastomosis of healthy trachea to a healthy larynx. This is a technically more challenging operation than laryngotracheal reconstruction with cartilage grafts (Figure 89.4).

Figure 89.4 Cricotracheal resection (continued over).

Figure 89.4 Cricotracheal resection (continued).

The success of CTR in infants and children has been documented in two large series of patients.^{12, 13} [**/*] The results reported are superior to those of the laryngo-tracheal reconstruction procedures for similar indications and stenosis grades. CTR with primary anastomosis is a safe and effective procedure for the treatment of severe subglottic stenosis in infants and children. Diagnostic precision is essential, operative timing should be judged carefully, and operative technique must be precise. The reasons for the high success rate include the complete resection of the stenotic segment with restoration of a lumen using a normal tracheal ring, the preservation of normal laryngotracheal support structures without disruption of the cartilaginous framework, and full mucosal lining on both sides of the anastomosis, thus minimizing or preventing granulation tissue and restenosis. The complications of the surgery, however, should not be underestimated. The first is injury to the recurrent laryngeal nerve. Typically, the recurrent laryngeal nerve is not identified during the procedure as it lies posterior to the cricothyroid joint and the resection margin is anterior to the cricothyroid joint. The second complication is dehiscence of the anastomosis, which is most likely

to happen if there is tension at the site of the anastomosis or because of forceful reintubation if the endotracheal tube becomes dislodged. In the paediatric larynx the technique of laryngeal release is not required in most cases of CTR. If mobilization of the trachea is difficult or tracheal resection is extensive (more than five tracheal rings), then laryngeal release should be performed to minimize the risk of dehiscence. If granulation tissue is allowed to grow there is also a risk of restenosis, and for this reason sutures through the cartilage should emerge submucosally at the edge of the anastomosis.

Experimental data in primates show that when CTR and primary tracheal anastomosis are performed with a good initial result, the thyroid cartilage and tracheal ring sutured together continue to grow normally. A further advantage of the CTR technique may be that voice quality should not deteriorate because the anterior commissure of the larynx is maintained in its initial position and there is no widening of the larynx posteriorly with an interposition graft. However, in older children, CTR may limit the ability to tilt the thyroid cartilage on the cricoid cartilage, in turn restricting cord tensioning and leading to a loss of vocal range.

CONTRAINDICATIONS

All contraindications to airway reconstruction are relative. Usually, airway reconstruction is not attempted unless decannulation is the goal. Gastro-oesophageal reflux disease and eosinophilic oesophagitis should be controlled preoperatively, and pulmonary function optimized. Operating on a child requiring pulmonary pressure support to ventilate adequately is unwise. Single-stage reconstruction is inadvisable in a child who is difficult to intubate. In children with a history of sedation problems, past failure of airway reconstruction or multiple levels of airway pathology, single-stage reconstruction should be approached with caution. In children undergoing CTR, the risk of anastomotic dehiscence seems higher in the presence of Down syndrome, MRSA or a past history of distal tracheal surgery. The greatest disservice to a child is for airway reconstruction to cause or exacerbate ongoing aspiration.

COMPLICATIONS

Complications may be subdivided into intraoperative, early postoperative and late postoperative.¹⁴ Intraoperative complications include bleeding, pneumothorax and loss of the airway with resultant hypoxia. Early postoperative complications include infection, air leakage from the operative site, dehiscence of an anastomosis and loss of a graft. The risk of air leakage and graft loss is highest when systemic steroid use is continued beyond two or three peri-extubation doses. With single-stage procedures there is a risk of accidental extubation, and risks associated with paralysis or sedation. Extubation may be compromised because of glottic oedema and granulation caused by the endotracheal tube. The most significant long-term complication is failure of the reconstruction with restenosis of the subglottis, with an incidence between 10 and 20 percent in most series.

Revision airway surgery/the recalcitrant airway

Failure of laryngotracheal reconstruction or CTR does not preclude further attempts at reconstruction, but may complicate further reconstructive efforts. In revision airway surgery, particular care should be taken to optimize the outcome by careful preoperative evaluation of the patient and their airway. Failed expansion cartilage grafting may still be amenable to either further cartilage grafting or resection, while failed resection may still be amenable to further resection or cartilage grafting.

KEY POINTS

- The narrowest point in the infant airway is the cricoid ring. The only fixed ring within the airway, it is the most vulnerable point for iatrogenic damage caused by intubation.
- Acquired subglottic stenosis secondary to prolonged endotracheal intubation remains the most frequent cause of laryngeal stenosis.
- Laryngeal stenosis continues to cause significant morbidity and mortality. The commonest primary aim of intervention is decannulation or preventing the need for tracheotomy. In selected patients, voice restoration or provision of a safer airway is the primary consideration, with decannulation a secondary goal.
- Evaluation of the paediatric airway should not be considered a minor procedure, particularly when performed in a child with an unstable airway. Extreme care must be taken not to exacerbate the child's condition.
- Rigid endoscopy remains the gold standard for paediatric airway evaluation.
- Laryngeal and upper tracheal reconstruction may be challenging; no single operation can address all types of laryngeal stenosis. It is prudent to evaluate each child on an individual basis.
- The most significant long-term complication of surgery for laryngeal stenosis is failure of the reconstruction with restenosis of the subglottis, with an incidence between 10 and 20 percent in most series.
- CTR has an increasing role in the management of subglottic stenosis. CTR is particularly effective as a salvage procedure following failed laryngotracheal reconstruction.
- The greatest disservice to a child is for airway reconstruction to cause or exacerbate ongoing aspiration.

Best clinical practice

- ✓ In the neonate who has failed extubation, the anterior cricoid split procedure is an alternative to tracheotomy. [Grade C]
- ✓ Preoperative evaluation of gastro-oesophageal reflux should be mandatory in a child with an active larynx or recalcitrant airway stenosis following previous reconstruction. [Grade B]
- ✓ Functional endoscopic evaluation of swallowing can provide valuable information about the risk and

mechanism of aspiration as well as the presence or absence of normal laryngeal sensation. [Grade B]

- ✓ In a child who has not been evaluated previously, flexible nasopharyngoscopy with the child awake should be performed prior to rigid endoscopy. [Grade D]
- ✓ In children with significant lung disease, decannulation may be imprudent. Children with progressive neuromuscular disorders, diaphragmatic weakness or central hyperventilation syndrome, may not be candidates for decannulation. [Grade C]
- ✓ In a child with a compromised airway who does not have a tracheotomy tube, preoperative administration of dexamethasone, 0.5 mg/kg up to a maximum of 20 mg, is a prudent precaution. [Grade B]
- ✓ Spontaneous ventilation offers the best dynamic assessment of the airway and is thus recommended. [Grade D]
- ✓ In children in whom a stenting period of less than two weeks is anticipated, consider intubation, with the endotracheal tube acting as the stent (see Single-stage reconstruction). [Grade C]
- ✓ A prerequisite for single-stage laryngotracheal reconstruction is an excellent ICU in which staff are familiar with the management of airway patients. [Grade D]

Deficiencies in current knowledge and areas for future research

- While laryngotracheal reconstruction and CTR have become accepted management techniques for subglottic stenosis, supraglottic airway management remains poorly understood and managed.
- Preoperative evaluation and optimization of patients prior to reconstructive airway surgery still requires refinement.
- Recent technological advances, such as impedance probe evaluation of gastro-oesophageal reflux, need critical evaluation.
- Paediatric voice research may be an area for future endeavour.
- An airway grading system that is not limited to just the subglottis needs to be developed.
- Tissue engineering techniques may offer alternatives to current methods of airway reconstruction.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words paediatric, voice and dysphonia.

INTRODUCTION

There have been tremendous advances in the understanding of voice disorders and their management in recent years. The subspecialty of phoniatrics has evolved principally in adults and this knowledge may now be applied to voice disorders in children. Disorders of voice – where the predominant symptom is hoarseness or ‘dysphonia’ – must be distinguished from disorders of speech, articulation and language. Speech and articulatory disorders are characterized by difficulty in producing speech sounds, often in the presence of normal laryngeal function. In language disorders, the child uses words and sentences inappropriately, again usually despite normal laryngeal function.

Voice disorders are largely a manifestation of laryngeal pathology. Six to 23 percent of 5–18 year olds have some form of voice ‘problem’.^{1,2} In the majority, neither the child nor their parents perceive the voice as a concern and they do not present for medical evaluation.

The spectrum of voice disorders seen in a specialist paediatric voice clinic is very wide. Patients range from child performers who have a normal conversational voice but whose parents have been concerned about a loss of the upper range of their singing voice, to children with severe congenital or acquired laryngeal disease with no voice at all.

With careful assessment, voice therapy and occasionally surgical intervention, most paediatric dysphonias can be corrected or improved.

GROWTH AND DEVELOPMENT OF THE LARYNX

The paediatric larynx is quite different from that of the adult (**Figure 90.1** and **Table 90.1**). The embryonic development of the larynx is described in detail in Chapter 162, Anatomy of the larynx and tracheobronchial tree. This section focusses on those aspects relevant to voice disorders and on normal growth and development after birth. Current knowledge stems largely from the detailed studies of Hirano *et al.*^{3,4}

Elongation of the vocal folds

Hirano found that up to the age of ten years, the length of the vocal fold was very similar in both males and females (6–8 mm). At puberty there is a substantial increase in growth, much more marked in males with the membranous vocal fold increasing to 14.8–18 mm (more than double). In females the increase is to 8.5–12 mm – an increase in length of a third. The cartilaginous portion of

Figure 90.1 *Table 90.1* Differences between the larynx of an adult and child.

Feature	Difference
Size	The paediatric larynx is relatively smaller
Position	The child's larynx is relatively higher
Shape	Curled epiglottis, shorter vocal folds
Mucosa	More reactive and prone to airway obstruction. Croup is uncommon in adults
The laminar vocal fold structure	Immature in young children

the vocal fold also grows with age but less rapidly, with a relative increase in the ratio of the membranous to cartilaginous vocal fold from 1.5 in the newborn to 4.0 in the adult female and 5.5 in the adult male. Hirano devised the concept of the respiratory glottis posteriorly with a wider aperture and the phonatory glottis anteriorly. These concepts are useful in planning surgical procedures. For example, in bilateral vocal cord paralysis it is possible to increase the airway by performing an ablative procedure, such as a laser arytenoidectomy. If this procedure is kept to the posterior part of the larynx then the anterior membranous vocal fold can be preserved for phonation.

Changes in vocal fold laminar structure

Much has been written about the layered structure of the vocal folds and its importance both to the understanding of disease and the development of phonosurgical treatment.

The five layers of the vocal fold are the *epithelium*, *superficial layer* of lamina propria (Reinke's space), the *intermediate* and *deep* layers of the lamina propria and the *muscle layer*. The first two are referred to as the 'cover' and move freely over the deeper layers which form the 'ligament' and 'body' of the vocal fold.

This laminar structure is not present at birth, but starts to differentiate over the first few months of life. It becomes more developed throughout childhood and the adult form is quite easily recognizable by puberty. One surgical implication of this is that microflaps are more difficult to raise in early childhood due to a less well-developed plane for dissection in the superficial lamina propria.

Changes in pitch

An important *feature* of the paediatric voice is its pitch. This drops throughout infancy and childhood in males and females, with a marked change at puberty, particularly in males. This change in pitch corresponds to the anterior growth of the thyroid cartilage in response to testosterone and coincides with the development externally of the thyroid prominence or Adam's apple. The fall in pitch is approximately proportional to the growth of the membranous vocal fold.

ASSESSMENT OF THE CHILD'S VOICE

Children with voice disorders can either be seen in a general clinic or in a voice clinic. An otolaryngologist and speech and language therapist should staff paediatric voice clinics. Videostroboscopic equipment and the expertise to use it should be available. The history and basic otolaryngological examination is the same in both settings. Whether laryngeal videostroboscopy and speech therapy assessment is required will depend on the clinical situation.

History and examination

Mild or moderate dysphonias that have been present for some time tend to be accepted as part of the child's personality and not a medical disorder. Often, an incidental remark years later leads to the parents seeking medical assessment to exclude an underlying disorder. Some children and families see no problem with their dysphonia. Alternatively, some children and families find a mild dysphonia very troublesome, particularly if they are performers or have aspirations to perform.

Information should be sought from both the child and parents. If the problem has been present from birth, a congenital lesion is likely. However, a history of endotracheal intubation around the time of birth or around the

time of onset of symptoms may suggest laryngeal stenosis, cricoarytenoid joint fibrosis, intubation granuloma or cyst formation. Much more commonly, symptoms start with an upper respiratory tract infection that has been accompanied by laryngitis, a situation made worse by habitual patterns of voice misuse.

The severity of the disorder may range from a loss of singing voice to complete loss of conversational voice. The time course of the dysphonia is also important. For example, dysphonia is often persistent with discrete vocal fold lesions and rarely returns to normal, although it may fluctuate and fatigue during the day.

Enquire about symptoms suggestive of gastro-oesophageal reflux, as this may irritate the larynx and cause dysphonia. Post-nasal drip associated with allergic rhinitis will do the same, particularly if there is a habit of forceful or constant throat clearing. Cough is quite harsh on the vocal mechanism and constant coughing associated with respiratory disease may lead to hoarseness.

Restrictive respiratory disease may cause reduced infraglottic pressure and subsequent dysphonia. The use of corticosteroid inhalers can also cause dysphonia and this can be helped by modification of drug regime or possibly inhaler technique and the use of spacer devices.⁵

Hearing loss may make the child shout. This can be the underlying cause of a dysphonia secondary to vocal misuse. Voice misuse – shouting – is common in children and may lead to disorders of hyperfunction such as nodules. Other abusive behaviours, such as smoking and alcohol, may occasionally be relevant.

It is extremely important to enquire about exercise intolerance and stridor, symptoms and signs that may be caused by laryngeal stenosis. Swallowing problems or choking may be the first indication of laryngeal paralysis. A general otolaryngological examination, including assessment of the ears and hearing, should be performed. Important clues can be gained by carefully listening to the quality of the child's voice during history taking. Laryngoscopy should be undertaken in all cases.

Laryngoscopy

The objectives of laryngoscopy are two-fold, first to identify any structural lesion, such as a vocal nodule or papilloma; second, to assess laryngeal mobility during phonation.

Older children may be cooperative enough for indirect laryngoscopy but examination of the paediatric larynx has traditionally been performed under general anaesthetic. Detailed structural information can be obtained but little information is gained with regard to mobility. It is usual to watch vocal mobility on awakening from general anaesthesia. This can provide information with regard to vocal paralysis, but it should be recognized that by today's standards this is a very crude method of assessment. Awake laryngeal and voice examination should be the standard of care in a compliant child.

Most focal lesions can be excluded by awake fiberoptic laryngoscopy. This can be performed on a child of almost any age. It is usually quite straightforward, performed transnasally with a 2.2-mm fiberoptic endoscope. The optics of the larger fiberoptic endoscopes are better and, if possible, a 4-mm endoscope should be used. From age one to five years, compliance is limited and general anaesthesia and microlaryngoscopy may need to be considered. Some images are of sufficient quality to permit stroboscopy with examination of the mucosal wave.

Rigid laryngoscopy requires significant cooperation, which can only be obtained in children over six years of age. High quality images of the larynx combined with stroboscopy give unparalleled information on vocal fold movement and structure. They also provide an important educational tool for parents and older children. Paralysis of a vocal cord is generally obvious but this technique gives insight to more subtle mobility disorders such as limited posterior glottic closure (glottic chink) and supraglottic constriction. This degree of information is useful and relevant to planning voice therapy.

SPECIFIC DISORDERS

Vocal nodules and functional voice disorders

Vocal nodules – now regarded as an organic manifestation of laryngeal hyperfunction – are the commonest cause of dysphonia in children (**Figure 90.2**).⁶ The mainstay of treatment is voice therapy to correct the hyperfunction. While in adolescents this therapy is similar to that employed in adults, different strategies are necessary in younger children.

The traditional view, based on clinical experience, was that most vocal nodules in children could be expected to improve at puberty.⁷ Puberty is a time of great change in the larynx, with tremendous growth of the membranous

© Hodder Arnold / Scott-Brown 7E

Figure 90.2 Vocal cord nodules.

vocal fold in the male and, to a lesser extent, in the female. One can see how the dynamics of vocalization might change with potential improvement in the nodules. Mori,⁸ however, reported that 12 percent of nodules did not improve at puberty. In the same study it was found that those treated with vocal hygiene alone (i.e. general advice regarding voice care) did not improve. Those given voice therapy under the supervision of a speech and language therapist did tend to improve and the degree of improvement was related to the number of therapy sessions. [**] The essentials of voice therapy include reduction of vocal strain. Various techniques can be employed to reduce shouting, whispering, coughing and throat clearing and to encourage the use of a smooth easy voice. Periods of quiet play are recommended after noisy activity (e.g. football) to allow vocal fold recovery.

Surgery for nodules is rarely recommended in children. Concerns about the potential effects of scarring are very real. On occasion it can be justified when prolonged voice therapy has failed. Bouchayer and Cornut⁹ reported cysts, polyps and sulci in children previously diagnosed as having nodules when examined at microlaryngoscopy. Some children with nodules have vocal cord cysts with a nodule on the contralateral cord and this might explain why some fail to respond to voice therapy. The use of videostroboscopic techniques in the voice clinic should help diagnose these conditions earlier. Cysts are treated by microsurgical excision.

A wide range of functional voice disorders can be demonstrated in children without demonstrable nodules. These children may present with dysphonia, or even aphonia, secondary to underlying psychological factors. For these children, voice therapy may need to be combined with a psychological assessment. Aphonia in the presence of a normal laryngoscopy evaluation is suggestive of psychological disturbance. A normal cough or laugh adds support to this contention. Puberphonia, when the prepubertal voice persists into adolescence or adulthood, is another condition associated with psychological disturbance. Highly specialized voice therapy, possibly in conjunction with a psychologist, is important to help these children develop an adult voice.

Laryngeal papillomatosis

A detailed account of laryngeal papillomatosis is given elsewhere (Chapter 91, Juvenile-onset recurrent respiratory papillomatosis). From the voice perspective, there are a number of important considerations.

The emphasis of modern surgical techniques is to minimize damage to the underlying lamina propria and to restrict surgery to the papillomas. In this way, voice quality will be optimized in the long term. Glottic scarring and webbing are well-known complications of surgical intervention with the laser.¹⁰ The use of a microdebrider and cold steel instruments has much to

commend it. After all, surgery cannot cure papillomatosis. Medical treatments have been advocated including intra-lesional acyclovir with some reported success.¹¹ [**] In theory, any medical adjunct that reduces the number of surgical procedures would be beneficial in terms of voice preservation, although voice outcomes following these therapies have yet to be reported. Cidofovir is showing some promise and its use is considered in Chapter 91, Juvenile-onset recurrent respiratory papillomatosis.

Intubation injuries and voice

Much has been written about acquired subglottic stenosis consequent on prolonged endotracheal intubation in premature infants. Surgical techniques have evolved to correct this abnormality and allow eventual decannulation.^{12, 13, 14} Voice problems following this surgery have been documented and are not uncommon.¹⁵

Subglottic stenosis is just one example of laryngeal injury caused by intubation. More minor scarring may affect the voice but not the airway (Figures 90.3 and 90.4). Damage to the vocal fold or underlying lamina propria causes dysphonia. Cricoarytenoid joint fixation and posterior glottic scarring may also be caused by endotracheal intubation and reduce vocal fold mobility. It is easy to confuse these conditions with vocal cord paralysis.

Voice therapy can be successful in some children. Surgical treatment of voice problems caused by intubation trauma remains a significant challenge. There is potential for the introduction of medialization techniques in this group of children, but there must be an adequate airway before this can be considered and this situation is uncommon.

Vocal cord paralysis

In general terms, children with bilateral vocal cord paralysis have a good voice or cry. It is the airway that gives concern. Spontaneous recovery of function takes place in some, but after two to three years of observation this is unlikely to happen.¹⁶ A number of lateralization procedures can be performed to develop a wide posterior glottis for respiration while preserving the anterior glottis for phonation. Either laser arytenoidectomy^{17,18} or endoscopic suture lateralization can achieve these goals.

In contrast to bilateral cord paresis, children with unilateral cord paralysis present with aspiration and a weak cry. The airway is relatively spared. Most improve with time due to compensation from the contralateral nonparalyzed vocal fold or to spontaneous recovery.

Medialization thyroplasty can be considered for those that do not improve and continue to have a significant voice problem. However, there is limited published information on this and it should be remembered that its efficacy to diminish aspiration has been limited.¹⁹

The concept of placing a silastic implant before puberty has raised concerns that this might interfere with the anticipated physiological growth spurt. It is the author's practice to consider medialization using a fat injection in dysphonic, prepubertal children and to restrict silastic thyroplasty techniques for dysphonic post-pubertal patients. [*]

The concept of reinnervation is attractive. In a series of eight children with unilateral vocal cord paralysis, three underwent implantation with ansa cervicalis/strap muscle pedicles. This, together with postoperative voice therapy, gave 'good' results.²⁰ There has to be some scepticism about these procedures as re-innervation techniques are capable of restoring laryngeal tone but have had limited success in achieving voluntary movement. Nevertheless, children seem to be the ideal population on which to

carry out these procedures as nerve grafting in general is more successful in this age group.

It is worth restating that it should never be assumed that an immobile vocal cord is paralyzed. Vocal cord immobility in previously intubated children may be due to joint fixation or posterior glottic scarring. The distinction between these diagnoses is extremely important, particularly when vocal cord immobility is bilateral. The management of paralysis is conservative with a tendency towards spontaneous recovery. Fixation and scarring do not improve and children may be subject to years of unnecessary waiting with a tracheotomy before a surgical lateralization procedure is contemplated.

Tracheotomy and voice

Children with tracheotomies will often have impaired voice. This is only partly due to the tracheotomy tube diverting air from the glottis. The main factor is usually the laryngeal lesion that required tracheotomy formation in the first place. Children with a healthy larynx can obtain good voice by occluding the tube on expiration (with a finger or speech valve) and projecting air around the tube and up through the glottis. To facilitate this, the tube needs to have sufficient space around it and may need to be 'downsized'. This is usually possible without restricting the airway. Speech valves are frequently used in the author's practice for children. As well as helping with speech they help with secretion management and swallowing. [*]

KEY POINTS

- Voice disorders in children are common; few require medical intervention.
- A diagnosis can usually be made by careful history taking and examination to include laryngoscopy and ideally videostroboscopy.
- Laryngeal muscle hyperfunction with or without nodules constitutes the commonest group of disorders.
- These disorders respond well to skilled voice therapy.

Best clinical practice

- ✓ Laryngeal microflaps are more difficult to raise in early childhood due to a less well-developed plane for dissection in the superficial lamina propria. [Grade A]
- ✓ An immobile vocal cord is not always paralyzed. Consider joint fixation and posterior glottic scarring, especially if the child has been intubated. [Grade B]

- ✓ The term 'vocal abuse', often used to describe adult dysphonias, is best replaced by 'voice misuse' in the paediatric setting. Beware the sensitivity of recording the word 'abuse' in children's records. [Grade D]
- ✓ Advances in endoscopic equipment are such that awake laryngeal and voice examination should now be the standard of care in a compliant child. [Grade C]
- ✓ Due to the potential for permanent scarring, surgery for nodules is rarely recommended in children. It should be considered only as a last resort when prolonged and skilled voice therapy has failed. [Grade B]

Deficiencies in current knowledge and areas for future research

- **Laryngeal transplantation for voice.** Perhaps the most challenging of paediatric voice conditions is the child with no voice due to complete laryngeal stenosis which is beyond surgical reconstruction. Such children are encountered after severe burns or caustic ingestion. They are tracheotomy dependent and communicate with signing and non-oral devices. Laryngeal replacement using transplantation carries the best hope for these children and although there has been one successful adult patient, this has yet to be repeated.
- **Reinnervation of the paralyzed larynx.** Phonosurgery can be helpful for the voice in laryngeal paralysis with medialization using injection or thyroplasty techniques. However, the biggest concern for children with laryngeal paralysis is not voice but aspiration. We do not have a universally accepted solution for aspiration due to laryngeal incompetence. Withdrawal of oral feeding and gastrostomy remains the mainstay. Fortunately, compensation frequently takes place for unilateral lesions but often not bilateral problems. Laryngeal reinnervation may hold the key but is still in its infancy.
- **Repair of damaged vocal cords with synthetic 'SLP'.** Vocal cords damaged by intubation or surgery have lost the mucosal wave due to destruction of the important superficial layer of the lamina propria (SLP layer). Medialization of damaged vocal cords has had only limited success and attempts are being made to create a synthetic substitute for this important gel layer for potential replacement by injection into Reinke's space.

SEARCH STRATEGY

The data in this chapter are supported by a PubMed (NLM) search using the key words respiratory papillomatosis and laryngeal papillomatosis.

INTRODUCTION

Recurrent respiratory papillomatosis (RRP) is a potentially life-threatening disease characterized by the development of papillomas anywhere in the respiratory tract from the nasal vestibules to the terminal bronchi. Predominant sites are where there is a change of epithelium, e.g. from squamous to ciliated, and especially the tonsillar pillars, uvula, vocal folds and laryngeal commissure. There is a bimodal age distribution with a juvenile-onset peak occurring at three to four years of age and an adult-onset peak occurring at 20–30 years of age. Boys and girls appear to be nearly equally affected in juvenile-onset RRP (JORRP). This contrasts with adult-onset RRP, which is a disease transmitted via sexual contact or via indirect contact with anogenital lesions, preferentially affecting men by a ratio of approximately three to two. Although adult-onset respiratory papillomatosis and juvenile-onset respiratory papillomatosis share many features, this chapter addresses only JORRP.

AETIOLOGY

Juvenile respiratory papillomatosis was first described by Morrell Mackenzie in 1880. By 1923, Ullmann had demonstrated an infective aetiology by injecting homogenized papilloma from a child's larynx into his own forearm and inducing local growth of papillomas. Further direct evidence of the association between human papilloma virus (HPV) and RRP came from the identification of HPV DNA within laryngeal papillomas by Southern blot hybridization and the subsequent recognition in papillomas of HPV types 6 and 11.¹ Human papillomavirus is a naked, double-stranded, icosahedrally-shaped virus with circular supercoiled double-stranded DNA genome surrounded by an outer capsid of protein that belongs to the Papovavirus family. There are 90 known subtypes of HPV – although many vary only slightly in their DNA sequence – but only types 6, 11 and rarely 16 are associated with RRP. HPV types 6 and 11 are also associated with condyloma acuminata (genital warts). Types 16 and 18 have been implicated in

carcinogenesis, particularly in the uterine cervix and in squamous cell carcinoma of the head and neck. HPV is thought to first enter traumatized epithelium and reside in the basal layer of the mucous membrane, where it replicates by a process known as episomal maintenance. This replication interferes with the normal process of cell maturation causing epithelial proliferation and neovascularization. Conversely, the virus may lie dormant causing subclinical infection and can often be recovered from apparently normal tissue adjacent to papillomas. Viral protein, DNA synthesis and virion assembly only takes place in the granular and cornified layers of the terminally differentiated epithelium.

EPIDEMIOLOGY

Juvenile-onset RRV is an uncommon condition, with a prevalence of only four in 100,000 children. The oft-quoted triad of susceptibility factors for JORRP – young mother, vaginal delivery and low maternal socioeconomic status – is of limited predictive usefulness.² Latent or active HPV has been detected in cervical swabs from 10–25 percent of women of childbearing age. The associations between HPV, JORRP and a history of maternal genital warts are well established but what is uncertain is the influence, if any, these associations should have on obstetric management. HPV DNA has been found in one-third to one-half of aerodigestive tract swabs of children born to affected mothers. However, the majority of these children do not develop disease. Calculations suggest that only one in 400 infants delivered to women with genital warts subsequently develop JORRP. This relative risk is much lower than that for sexually transmitted diseases. The discrepancy between the incidence of HPV colonization of the aerodigestive tract of the infant and the incidence of RRP implies that host factors must be involved in determining susceptibility. Although a history of maternal genital warts is not universal, a large retrospective study has shown that children born to mothers with genital warts carry a 231× relative risk of developing JORRP. A prolonged delivery time (exceeding ten hours) conferred a two-fold increased risk but delivery by Caesarean section did not appear to reduce that risk.³ The evidence for protection from vertical transmission of HPV into the baby's upper respiratory tract by Caesarean section is conflicting and therefore the decision on method of delivery must be made on a case-by-case basis. Current evidence does not warrant Caesarean section as a prophylaxis against RRP.

Variation in the susceptibility of the host to viral infection may be associated with specific HLA polymorphisms, several of which have been reported. Two recent, large independent studies have shown an association between HLA-DRB1*0301 and severe disease.^{4,5} T-cell responses were shown to be the same by one group between HLA-DRB1*0301-positive patients and negative

controls, leading to speculation that the clinical severity of disease is due not to a failure of T-cell proliferative response to HPV, but a delay in that response due to a low frequency of HPV-specific T cells or modulation of the T cell response by immunoregulatory networks.⁵ Bonagura *et al.*⁴ showed that HLA-DRB1*0301-positive patients exhibited reduced interferon-gamma expression. While the associations between JORRP and HLA-genotype are being increasingly well recognized, the underlying mechanism for evasion of the cellular immune response is far from clear.

CLINICAL PRESENTATION

Although respiratory papillomas can arise in any respiratory mucosa, their initial presentation is usually in the larynx. The diagnosis requires the surgeon to have an awareness of the condition as the presenting symptoms can be variable and mimic many common laryngeal and respiratory pathologies in children. In addition to hoarseness and stridor, children may present with a chronic cough, paroxysms of choking, recurrent respiratory infections or failure to thrive. These latter symptoms may lead to a misdiagnosis of asthma, laryngitis, bronchitis or croup and a delay of diagnosis of JORRP of up to eight years.¹

DIAGNOSIS

If at all possible, the clinical diagnosis should be established with awake fibreoptic nasolaryngoscopy (using an infant 2.2 mm endoscope) because the difficulties presented to the anaesthetist by unexpected laryngeal papillomas prolapsing into and obstructing the glottis cannot be overstated.^{6,7,8} The preferred anaesthetic technique in our institution is that of spontaneous respiration without endotracheal intubation. General anaesthesia is induced either by intravenous propofol or, more frequently, by inhalation of sevoflurane in oxygen. The larynx is topically anaesthetized with 2 percent lidocaine and anaesthesia maintained by sevoflurane in oxygen through a nasopharyngeal airway, of a size and length appropriate for the child's age. This allows excellent surgical access to the airway but carries the disadvantage that the lower airway is not directly protected from bleeding. Therefore, meticulous haemostasis is required during the procedure using topical epinephrine (1:10,000 applied on neurosurgical patties). Regardless of the surgical technique, it is important for the child to recover from anaesthesia with humidified oxygen. Many units use preoperative dexamethasone to reduce laryngeal oedema but some surgeons feel that antiinflammatory agents are best avoided during active manipulation of papilloma tissue. Laryngopharyngeal exposure to gastric acid is increasingly being recognized

as a cause of laryngeal pathology. This is particularly relevant during the immediate postoperative period where laryngeal mucosa has been breached.⁹ Therefore, it is our practice to give prophylaxis against gastro-oesophageal reflux with an H₂-antagonist or a proton pump inhibitor for 48 hours after all laryngeal surgery including surgery for JORRP. [*]

Macroscopically, papillomas can be pedunculated or sessile, spread over the mucosal surface of the larynx (Figure 91.1). They tend not to be friable and can be grasped using microlaryngeal instruments and excised for histological examination. **Microscopically**, the papillomas appear as exophytic projections of keratinized squamous epithelium overlying a fibrovascular core, with varying degrees of dyskeratosis, parakeratosis and dysplasia. Koilocytes (vacuolated cells with clear cytoplasmic inclusions) are often seen indicating viral infection.

STAGING

Staging of disease is not universally undertaken even in units with a large case-load of RRP. The staging system proposed and modified by Derkay^{10, 11} is based on a combination of the anatomical distribution and extent of lesions and their clinical effects on voice and the child's airway. It is increasingly used by members of the American Society of Pediatric Otolaryngologists (ASPO). Widespread adoption of a universally agreed staging system would enable comparison of results between centres and facilitate multi-centre trials, particularly of adjuvant treatments.

TREATMENT

The aim of surgical treatment for recurrent respiratory papillomatosis is the removal of papillomas and restoration of a normal airway while minimizing trauma to the

Figure 91.1 Recurrent respiratory papillomatosis in the larynx.

mucosa and vocal cords. In children requiring repeated extirpations of extensive papillomas, especially if they predominantly occur in the larynx, it may be ultimately impossible to achieve normal voice. It is in these patients that the surgical technique, balance of the extent of lesion removal against interval timing, and application of adjuvant therapies must be combined and finely judged to ensure minimal dysphonia and airway stenosis, both of which can be extremely difficult to manage.

Surgical treatment

POWERED MICRODEBRIDER

The use of the powered microdebrider is a relatively new development in the surgical removal of laryngeal papillomas, but one which has become the gold standard for papilloma removal in the larynx (Figure 91.2).¹² The laryngeal debrider blade allows gentle but comprehensive removal of papillomas with minimal contamination of the lower respiratory tract with blood or papillomas. There is no thermal trauma and using direct endoscopic control it is extremely precise with minimal mucosal damage. Small retrospective studies demonstrate that, compared with the CO₂ laser, patients undergoing laryngeal papilloma debriement have good disease clearance, require a shorter procedure and experience less postoperative pain. One retrospective study showed no incidence of delayed soft tissue complications using the microdebrider.¹³ Long-term results of this are still awaited, but early results are extremely promising.^{14, 15, 16} [**]

COLD STEEL SURGERY

Advocates of papilloma removal using microlaryngeal instruments claim that the use of a microflap technique minimizes trauma to the vocal fold while satisfying disease clearance. Thermal damage to neighbouring tissue is also avoided as is the vapour plume. Cold steel surgery has the distinct disadvantage of having no direct haemostasis when dealing with a very vascular lesion. Nevertheless, such surgery is successful in the hands of the exponents of this technique. [**]

CO₂, KTP, ND:YAG AND PULSED-DYE LASER

The carbon dioxide (CO₂) laser has been, for many years, the mainstay of surgical management of JORRP. It remains the treatment of choice for many surgeons because of its ability to ablate the papillomas with minimal bleeding and its ease of use with a microscope and micromanipulator. However, the frequency of late soft tissue complications, such as vocal fold fibrosis, interarytenoid fibrosis and stenosis, glottic webbing and

Figure 91.2 (a) Microdebrider; (b) close-up of blade.

arytenoid fixation, has been reported to be 13–45 percent.^{6, 17, 18} This increases with frequency of treatment and the number of laser ablations the child has received. Soft tissue complications can be minimized by appropriate laser settings and careful assessment of depth of ablation. A Japanese group has suggested, based upon a single case, a two-stage procedure whereby the bulk of the papillomas are removed at the first operation, which is then followed by a repeat endoscopy and laser ablation ten days later, by which time the coagulum and carbonized tissue have resolved, allowing a more precise laser clearance of residual papillomas.¹⁹ It is also important to have an effective plume extractor. This serves to allow a clearer image of the larynx, but also removes the potentially infectious laser vapour plume which carries a significant viral load. The latter may be simple conjecture as there has only been one reported case of a surgeon developing laryngeal papillomas with a history of repeated laser treatment to a patient with anogenital condylomas, *in situ* hybridization showing HPV types 6 and 11 in both the patient's and his lesions.²⁰

The KTP laser and the Nd:YAG laser are as effective as the CO₂ laser in papilloma ablation and haemostasis but, in addition, can be delivered through an optical fibre. Fibre-delivered laser systems play a role predominantly in the treatment of tracheal and bronchial papillomas. A new fibre-guidance system with a bendable distal tip developed for the Nd:YAG laser achieves a 50° range of directional manoeuvrability with minimal power loss.²¹ In adult patients, the delivery of pulsed-dye laser through a flexible bronchoscope can render it an outpatient procedure.²²

The pulsed-dye laser has attracted much interest in recent years. The advantages of the pulse-dyed laser are that it can be fibre-delivered and causes minimal vocal fold fibrosis and consequently minimal voice damage. However, it also distinguishes itself from the other forms of laser treatment in its mode of action. Rather than direct vaporization of tissue, it has been proposed that the 585 nm pulsed-dye laser is a vascular laser which causes photoangiolysis of sublesional microcirculation, denaturation of epithelial basement membrane linking

proteins, and cellular destruction.²² Therefore, it is less effective against large exophytic lesions and can be used as an adjunct to surgery either before or after the laser application.²³ The application of the pulsed-dye laser in the paediatric population is still under evaluation, but the results in adults with recurrent respiratory papillomatosis are very encouraging. [**]

PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) relies upon the observation that rapidly proliferating tissue selectively takes up a number of photosensitizing agents when administered intravenously, and that these agents release tumoricidal oxygen derivatives when activated by laser light of the appropriate wavelength. A non-blinded randomized prospective trial using dihaematoporphyrinether (DHE) at two different doses in combination with 50 J of 630 nm argon laser light was compared with laser treatment alone. The patients remain photosensitive for six to nine months and may experience skin erythema, blistering and ocular discomfort. Patients on the higher dose of DHE (4.25 mg/kg body weight) were reported to show a significantly larger decrease in papilloma growth rate but, despite that, only approximately half of the 48 patients receiving DHE showed a response, and no response was seen in patients previously treated with PDT.²⁴ A further randomized trial by the same group using meso-tetra (hydroxyphenyl) chlorin (mTHPC) as a photosensitizer showed reduction of severity of laryngeal papillomas in the mTHPC group, but this was not maintained and there was no effect on tracheal disease.²⁵ It should be noted that this trial only recruited 23 patients of whom only 15 patients completed the study. In both trials, there was a combination of juvenile-onset and adult-onset patients. [****]

Adjuvant therapy

Adjuvant medical therapies can be broadly divided into antiviral therapies and drugs with antiproliferative or

immunomodulatory properties. Vaccines and gene therapy remain in the early experimental stages.^{26, 27, 28} The decision to implement adjuvant therapy must depend on a careful consideration of the benefits against potential adverse effects of the therapy.²⁹ Adjuvant therapies which have been described in isolated case reports have been included for reference because while their use in 'routine' cases may not be justified, one may wish to consider their use when other better-tested avenues are exhausted.

INTERFERON- α

Interferons are naturally produced by human leukocytes, although as a pharmaceutical, interferon is now produced via recombinant DNA technology. Interferon- α can claim to have antiviral, antiproliferative and immunomodulatory properties. Interferons exert an indirect antiviral action by interfering with normal host cell translation mechanisms and by inducing synthesis of intracellular enzymes that act to control viral growth. By depleting essential metabolites in papilloma cells, interferon- α increases the length of their multiplication cycle, thereby slowing target cell growth. Interferon- α also facilitates recognition of papilloma cells by circulating leukocytes by enhancing expression of cell surface antigens. It is administered systemically by subcutaneous injection at a dose of 2–5 MU/m² of body surface area.³⁰ It is also the most well-studied of the adjuvant therapies for JORRP. A large randomized trial of 123 patients showed significant reduction in papilloma growth rate within the interferon arm. However, this was only significant for the first six months and the difference was not statistically significant during the second six months.³⁰ In another randomized crossover trial of 66 children, there was significant reduction in disease bulk in the interferon arms of the trial.³¹ This was extended to longer follow-up, at which data on 60 children were still available, showing complete remission in 22 children, partial remission in 25 patients and no response in 13.³² [****] The main problem preventing more widespread use of interferon- α is that there are many serious, idiosyncratic and unpredictable side effects including pancytopenia, hepatorenal failure and cardiac dysfunction. There is also a rebound phenomenon associated with withdrawal of the drug therapy. There is anecdotal evidence of the use of intralesional interferon in combination with laser debulking of JORRP, but this has not found widespread use.³³

CIDOFOVIR

Cidofovir is an acyclic nucleoside phosphonate which is active against a broad spectrum of DNA viruses including cytomegalovirus, Epstein-Barr virus and HPV. Its mechanism of action is by inhibition of viral DNA polymerases essential for viral replication. The principal application of this drug has been in the treatment of

cytomegalovirus in human immunodeficiency virus (HIV)-infected patients by intravenous injection. This mode of administration and high doses is associated with neutropenia and nephrotoxicity. Intralesional injection of cidofovir into JORRP is not associated with similar side effects. A canine model has shown that local irreversible soft tissue damage could be avoided in twice weekly cidofovir injections if the dose is limited to below 40 mg/mL.^{34, 35}

Based on their animal work, Chhetri and Shapiro³⁶ have proposed a schedule for treatment of JORRP based on intralesional injections of cidofovir at a concentration of 1 mg/mL. Injections were given at two-weekly intervals for four treatments and then the interval between treatments extended by one week after each and every subsequent treatment. Concomitant laser surgery was reserved for bulky lesions. Five patients were treated with this schedule with a mean follow-up time of 66 weeks. The mean papilloma stage decreased from 9.2 at initial presentation to 3.4 within two weeks of the first injection, and continued to decrease for the remainder of the follow-up period. After nine weeks of treatment, no patients required further laser surgery. Other studies have used cidofovir at the higher dose of 5 mg/mL with varying schedules of administration. Pransky *et al.*'s study³⁷ with a long follow-up (51.6 months) of 11 patients who had all previously required surgical debulking at two-to-six-week intervals showed a reduction in papilloma score in five, complete disease remission in five and one patient who continued to require treatment. In a more recently reported study with a mean follow-up of 30 months, 11 children were treated with intralesional cidofovir of whom five required no further treatment, four had an initial remission but relapsed and two had no apparent response. The authors counsel caution that the potential long-term carcinogenic effects of cidofovir are unknown and a 'response' may be related to the natural history of the disease.³⁸

RIBAVIRIN

Ribavirin is a synthetic nucleoside which has activity against a broad spectrum of viruses, but which is principally used as an aerosol in the treatment of respiratory syncytial virus pneumonia and systemically in the treatment of hepatitis C. There have been reports of its use both as an aerosol and systemically.^{39, 40, 41} However, these remain anecdotal reports and ribavirin is not widely used as an adjuvant treatment of JORRP. [*]

ACYCLOVIR

The evidence on the efficacy of acyclovir is weak and conflicting.^{42, 43} Although HPV is a DNA virus and acyclovir has a medium spectrum of antiviral activity, it does not directly inhibit HPV. Acyclovir is a nucleoside

analogue, which **inhibits thymidine kinase**, which is present in herpes simplex viruses (HSV) but not HPV. Adult patients, but not paediatric patients, with RRP have been shown to have molecular evidence of coinfection with other viruses, particularly HSV which may have a potentiating effect on HPV. It has been suggested that the mechanism of action of acyclovir is to eradicate HSV, thus removing this synergism. Side effects are rare and include nausea, vomiting, diarrhoea, fatigue and headache. [*]

INDOLE-3-CARBINOL

Indole-3-carbinol is a substance **derived from cruciferous vegetables** (e.g. **cabbage, broccoli, Brussels sprouts**), which has been shown to alter growth patterns of JORRP cell cultures *in vitro*. **It affects oestrogen metabolism, shifting production to antiproliferative oestrogen.** A prospective observational study with a mixed adult and paediatric population who received indole-3-carbinol as an adjunctive treatment to surgical removal showed partial or total responses in 21 of 33 patients. Within the paediatric subgroup, four out of nine showed partial or total response with no evident side effects.⁴⁴ [**]

CIMETIDINE

Cimetidine – a histamine receptor type 2 (H₂) antagonist – has been reported as a useful treatment for cutaneous warts. It has also been successfully used in treatment of an 11-year-old boy who had an eight-year history of diffuse conjunctival papillomas. The mechanism for this is attributed to **immunomodulatory side effects of cimetidine at high doses.** There is a single case report of very advanced JORRP with tracheo-bronchial-pulmonary involvement being treated successfully with adjuvant cimetidine at a dose of **40 mg/kg for four months** with remarkable improvement.⁴⁵ [*]

NATURAL HISTORY

The natural history of RRP is **extremely variable**. This makes it difficult for the surgeon to be able to reliably counsel the anxious parents on how their child's pathology will behave or at what age they might expect remission. Pathologically, **severe disease is strongly associated with HPV-11 infection** and thus patients should have viral typing as part of their initial pathology work-up. Poor prognostic signs include **onset of disease before the age of three years**, and **birth by Caesarean section**. In the United States, Medicaid insurance – often seen as a proxy measure of **low socioeconomic status** – is also associated with severe disease.⁴⁶ However, there are no other studies showing correlation between socioeconomic status and disease severity. Most affected children require **debulking of papillomas at two-to-three**

month intervals during periods of disease activity. Severe disease may necessitate **weekly surgical intervention** to prevent airway obstruction from rapidly growing papillomas. **The median number of debulking procedures required in a patient is reported to be 7–13.**^{47, 48} Not surprisingly, the repeated debulking of laryngeal papillomas **results in chronic voice changes**. Objective assessment of voice by GRBAS scale and Visi Pitch II 3000 acoustic analysis has shown significant difference between JORRP patients in remission and normal controls, but a Voice-Related Quality of Life Questionnaire (V-RQoL) showed that the dysphonia does not have any impact on quality of life.⁴⁹

There is a **tendency for remission in the early teenage years** and this has been attributed to hormonal changes occurring with the onset of puberty. Interestingly, **women with adult-onset RRP commonly experience severe exacerbations of their disease during the hormonal fluctuations of pregnancy.** What is clear, however, is that **remission is not related to the clearance of HPV from the mucosa** as viral DNA is detected in previously affected mucosa in patients in remission as well as in normal mucosa of patients with active disease.⁵⁰

TRACHEOBRONCHIAL DISEASE

Extralaryngeal spread of JORRP occurs in approximately **one-third of patients** with tracheal involvement in approximately one-quarter of patients. **Tracheal involvement may appear as cobblestoning of the mucosa coupled with the presence of papillomas.** **Factors predisposing to tracheal spread include the presence of subglottic papillomas, presence of a tracheostomy and a long duration of disease.**⁵¹ More distal bronchopulmonary involvement is reported in 4–11 percent of children with longstanding disease and may result in obstructive pneumonias.³⁰ Patients may develop cavitory pulmonary lesions leading to fever, sepsis and pulmonary atelectasis. Radiographically, these lesions may appear as solid or cystic pulmonary masses (**Figure 91.3**).⁵² A high index of suspicion must be maintained for malignant degeneration of bronchopulmonary lesions.

TRACHEOSTOMY

The indications for tracheostomy in patients with JORRP continue to divide clinicians. The source of this debate is that tracheostomy essentially constitutes an iatrogenic squamociliary junction and **may present an additional area of predilection for papillomas.**⁵³ However, it is not universal that all patients with a tracheostomy develop stomal papillomas. A tracheostomy in patients with severe disease may be life-saving and may also facilitate a longer interval between debulking procedures to restore some normality to the child's life.

Figure 91.3 Chest radiograph showing extensive pulmonary involvement with papilloma.

MALIGNANT DISEASE

Malignant degeneration of papillomas is a rare but devastating sequel. It is universally fatal.⁵² Irradiation of papillomas dramatically increases the risk of malignant transformation but as this is no longer used as a treatment modality, it is only of historical relevance. Most instances of malignant transformation have been reported in adult patients and have been associated with other risk factors including tobacco use and long-standing disease. Malignant transformation appears to be more likely with HPV 16, an unusual cause of JORRP, but HPV 6 and 11 have been shown to oncogenically transform cell culture lines *in vitro*. In adults, malignant degeneration usually involves the larynx, unlike children where cancer usually develops in the bronchopulmonary tree. Approximately 20 paediatric cases of malignant degeneration have been reported, all of which have been fatal. The currently proposed mechanism of malignant transformation involves oncoproteins E6 and E7. HPV types 6 and 11 produce transforming oncoproteins E6 and E7 that have been implicated in growth dysregulation through their ability to inactivate the tumour suppressor proteins p53 and the retinoblastoma tumour-suppressor gene product (pRb). The inactivation of the tumour suppressor genes results in a loss of control over proliferation and cell division and contributes to the development of the malignant phenotype. It is also becoming clear that the E6 and E7 proteins function to promote tumorigenesis through direct interactions with cell-cycle regulatory proteins. Unfortunately, apart from heightened vigilance, there is little to aid the clinician in predicting the rare cases of malignant transformation. There is no evidence of a papilloma-carcinoma sequence while p53 over-expression is variable and not a marker of

malignant transformation.⁵⁴ HPV expression may be lost in malignant transformation but this may not be a sufficiently robust clinicopathological predictor.

KEY POINTS

- Juvenile respiratory papillomatosis can affect any part of the respiratory tract.
- While it is uncommon, its management can constitute a major surgical burden to the otolaryngologist.
- The mainstay of treatment is by surgical debulking.
- The role of adjuvant therapy is uncertain but supported by level 3 evidence.
- In the majority of cases, the disease goes into spontaneous remission.
- Some children develop uncontrolled disease, which may be fatal.

Best clinical practice

- ✓ Current evidence does not warrant Caesarean section as a prophylaxis against RRP. [Grade B]
- ✓ Ideally, the clinical diagnosis should be established with awake fiberoptic nasolaryngoscopy prior to general anaesthesia. [Grade D]
- ✓ Patients should have viral typing as part of their initial pathology work-up. [Grade C/D]
- ✓ The powered microdebrider is quickly becoming the 'gold standard' for papilloma removal in the larynx. [Grade C]
- ✓ Spread to the tracheobronchial tree is associated with a greatly worsened prognosis. [Grade C]

Deficiencies in current knowledge and areas for future research

- JORRP has a great impact on the child's life during active disease and constitutes a big surgical load for the surgeon. While the majority of patients enjoy spontaneous remission, a small number continue to develop distal disease which may be fatal. Improvement in surgical technologies have reduced operative time and improved operative morbidity.
- The powered microdebrider has been a significant advance and better and more precise microdebriders seem likely to be developed.
- There is consistent level 3 evidence that cidofovir extends the treatment interval and promotes

remission of disease. Consolidation of this evidence will require multicentre collaboration in order to standardize protocols and increase patient recruitment. Such a multicentre initiative has already been proposed to seek critical genes in the pathogenesis of RRP.⁵⁵

- The future of the management of RRP lies in a better understanding of its pathogenesis.
- A vaccine against HPV has become available just as we go to press. Its main use will be in the prevention of cervical cancer in women but at least one type of vaccine ('quadrivalent vaccine') is active against HPV types 6, 11, 16 and 18 and may have a role in the prevention of RRP.⁵⁶ Trials are likely to get underway in the next few years with the added possibility of a therapeutic role for the vaccine in children with established RRP.
- Despite extensive and sophisticated molecular immunology research, the precise relationship between the human papilloma virus, host immunity and the development of papillomas eludes us. The elucidation of this relationship holds the key to conquering this disease.

Key points	1191		

SEARCH STRATEGY

The data and opinions presented in this chapter are supported by a Medline search using the key words child, foreign body, ear, nose, throat, larynx, trachea, bronchus, pharynx and oesophagus.

INTRODUCTION

Nature determined that we possess seven orifices. The otolaryngologist deals with five. Children are naturally curious about their surroundings and about these orifices! They are inclined to place toys, foodstuff and household articles in the ear, nose or the oral cavity. Sometimes the culprit is a sibling or a playground or nursery chum. Foreign bodies lodged within the ear, nose, larynx, trachea, pharynx or oesophagus may present as a minor irritation or a life-threatening problem.

FOREIGN BODIES IN THE EAR CANAL

An aural foreign body is an object not derived from the individual's own external ear, lying within the external auditory canal. Although the pinna is a part of the external ear, diseases of the pinna are covered in Chapter 236, Conditions of the pinna and external auditory canal; Chapter 236g, Acquired atresia of the external ear; Chapter

236i, Perichondritis of the external ear; and Chapter 236m, Haematoma auris; and foreign bodies of the pinna (e.g. ear-rings and studs) are not discussed in this chapter.

Foreign bodies within the external auditory canal can be classified as inanimate or animate (e.g. live insects). Inanimate objects can be inert or corrosive/irritant, organic or nonorganic and hydrophobic or hydrophilic.

Presentation

Although it is usually children that present with aural foreign bodies, self-instrumentation of the ear canal not infrequently brings the embarrassed adult to the otolaryngologist.

Inert foreign bodies may be completely asymptomatic and go unnoticed for many weeks, months or even years. Many patients complain of irritation, deafness, otorrhoea or tinnitus. Gradual wax impaction medial to a small foreign body may lead to a later presentation due to the disruption of the physiological keratinocyte migration.

The isthmus is the narrowest part of the external auditory canal and objects frequently impact at this point. Objects lateral to the isthmus are usually more readily removed.

In a review of 191 aural foreign bodies, 74 percent were in children aged seven or under, with beans, pebbles, beads (**Figure 92.1**), insects and small toys being the most common objects.^{1,2} Although parents and primary care health personnel are often worried about the possibility of residual perforation of the eardrum, this is uncommon unless there is unskilled instrumentation in attempted removal.

Button batteries are arguably the most dangerous foreign body in the ear, producing tissue necrosis as the alkaline fluid seeps out of them. The tissue necrosis then produces granuloma formation. Symptoms which can mimic malignant otitis externa can also develop.³

Insects in the ear can produce very distressing symptoms and the removal of live, moving insects can exacerbate oedema and trauma (especially where multiple bites and/or stings occur).⁴ [**]

Management

In a cooperative awake patient, the majority of foreign bodies can be removed with ease. General anaesthesia may be required for removal of up to 30 percent of objects, especially in the paediatric population.¹ Removal of foreign bodies in an uncooperative child can result in trauma, such as lacerations or tympanic membrane perforation which can occur in between 10–47 percent of cases.^{2,5} If an object is not removed easily on the first

attempt, referral to an otolaryngologist is essential to minimize further trauma to the child.^{5,6}

In a large review of 603 patients, the presence of a spherical foreign body, an object near the tympanic membrane and delay of 24 hours following insertion were identified as high risk factors for poor outcomes.⁷

In a review of the management of aural foreign bodies in an emergency department, when an object was graspable (e.g. a piece of plastic), emergency staff could remove it in 64 percent of cases with a complication rate of 14 percent, whereas if the object was non-graspable (e.g. a bead), only 45 percent could be removed (with 65 percent being referred to an otolaryngologist) with a 70 percent complication rate.⁸

Where objects are not removed rapidly otitis externa can develop and, if this is not treated, complications can rarely include mastoiditis and deep neck space infections.⁹

Techniques for removal include irrigation, suction, instrumentation or a combination of the three.⁶ The use of irrigation is naturally contraindicated for extracting hydrophilic items such as peas, beans, other vegetable matter or tissue paper. The use of the otomicroscope has been shown to produce a higher success rate for foreign body removal.⁷ The technique of extracting a spherical or ovoid item from the canal is to slide a wax hook over the top of it and then rotate the hook to engage the object and pull it out of the canal. Do not attempt removal by forceps as this results in it slipping further away. Superglue™ (cryanoacrylate) impregnated into cotton-buds can be used to aid aural foreign body removal,¹⁰ although it is significantly slower than using hooks and other standard instruments.¹¹ Superglue probes are particularly useful for the management of smooth foreign bodies such as beads or beans impacted at the isthmus.¹² Unwanted superglue in the external auditory canal is a particularly troublesome problem. Although some individuals will require surgical removal via an end-aural incision,¹³ there are now case reports of the use of acetone¹⁴ and warm 3 percent hydrogen peroxide¹⁵ which suggest these conservative techniques may be worth trying before subjecting a child to general anaesthesia. Repeated unsuccessful attempts at foreign body removal by an inexperienced practitioner will distress an anxious child and may compromise the options open to an otolaryngologist. If there is any doubt whatsoever about the potential success of an attempted extraction, then referral to a specialist is indicated.

The otolaryngologist should have a low threshold for arranging a semi-urgent admission for general anaesthetic removal if conservative methods fail. Urgent removal can only be justified for battery removal, or where severe oedema and symptoms exist. Rarely, an end-aural incision may be necessary to remove the foreign body.¹⁶

Studies comparing management options for aural foreign bodies are few in number.

For alive, animated foreign bodies, an *in vitro* study involving 17 test preparations showed that 95 percent

Figure 92.1 Foreign body (bead) in the ear canal.

ethanol killed all test insects in the fastest time (median 27 seconds). Oils performed poorly (51 seconds) and water and saline were particularly slow (180 seconds).⁴ [***]

NASAL FOREIGN BODIES

Presentation and management

Nasal foreign bodies are most common between the ages of two and five.¹⁷ They may be inert, hygrophilic or corrosive. Soft objects such as sponge fragments or tissue paper are the commonest to be found in the nose, in contrast to the hard objects inserted into the ears.² As is the case in the ear, small button batteries can produce devastating tissue damage and necrosis including septal perforation in a short time.¹⁸ A nasal foreign body may remain *in situ* for weeks and only present with a unilateral nasal discharge, often with a pronounced vestibulitis (Figure 92.2). Rigid endoscopes provide excellent visualization and can potentially minimize mucosal trauma. Although it has been claimed that a 4 mm rigid nasendoscope can be passed with ease in children as young as two years of age without decongestion,¹⁹ with the increased availability of smaller 2.7 mm endoscopes, it is the author's practice to use decongestion and as small an endoscope as possible in the paediatric population. The use of nebulized adrenaline provides excellent nasal decongestion and can greatly facilitate removal of foreign bodies, either by nose blowing or using instrumentation.²⁰ In general, the clinician has to make a clinical judgement as to what is going to be the best method for removal of a foreign body,¹⁷ bearing in mind that a child is unlikely to tolerate repeated manipulation and the doctor will only have one attempt at using a method that is going to cause any pain whatsoever. Magnets may be of use²¹ and nasal washing has been proposed as a method of removing foreign bodies, but is not widely practised.²² Superglue can also be effective.²³ The use of oral positive-pressure techniques has now been shown to be an effective way of removing anterior nasal foreign bodies.

Figure 92.2 Nasal vestibulitis due to a neglected foreign body.

© Hodder Arnold / Scott-Brown 7E

An oral Ambubag can be used²⁴ (three patients, 100 percent success) but the 'parent's kiss', where the carer blows into the open mouth of the child whilst occluding the contralateral nostril, is probably less traumatic for the child. Reported success rates vary from 79–100 percent.^{25, 26} The use of a 'Fogarty' embolectomy balloon catheter is another excellent way to easily remove foreign bodies from the nasal cavity and in one series of 25 patients, successfully removed 23 foreign bodies (92 percent) without the need for a general anaesthetic.²⁷

The possibility of inhalation into the tracheobronchial tree²⁸ needs to be borne in mind when managing a child with a nasal foreign body. [**] This is remarkably uncommon and is probably only a significant risk in the neurologically compromised child who has a poor gag reflex. If a nasal foreign body slips back into the nasopharynx it will usually be swallowed or expectorated. No complication of barotrauma to either the ears or lower airway has been reported in the literature search employed for this chapter.

Rhinolith

A rhinolith is a partially or totally calcified mass of tissue in the nasal cavity which may form around a foreign body nidus or can develop *de novo*.^{29, 30} They usually have a laminated structure, suggestive of a pathophysiological mechanism that involves layers of mucin aggregating around the foreign body. Each mucin layer subsequently becomes calcified, perhaps aided by the presence of turbulent air currents. They are classified as endogenous when they form around normal body material, such as blood clots, misplaced tooth remnants or bony sequestra. Exogenous rhinoliths form around foreign bodies inserted into the nose – usually of nonhuman material.^{29, 30} They can cause considerable symptoms, including nasal obstruction, purulent nasal discharge, rhinosinusitis and septal perforation.^{29, 30} They frequently require a general anaesthetic and transnasal removal, with or without fragmentation of the rhinolith.³¹

INGESTED FOREIGN BODIES

These may be swallowed and impact in the pharynx or oesophagus, or inhaled and obstruct the larynx or tracheobronchial tree. Either may prove fatal. Ingested foreign bodies in children represent a major global public health problem.^{32, 33} Coins, toys and food particles are the principal dangers, although regional and cultural factors in part dictate the frequency with which different objects occur.³⁴ Fish bones in the pharynx are commonly encountered in the Far East and in Greece. In Turkey watermelon seeds are the most frequently aspirated objects.³⁵ Coins are a universal danger particularly for pharyngo-oesophageal impaction

and nuts for tracheobronchial aspiration.^{32, 36} Nonspherical objects equal to or less than 1.5 inches (38.10 mm), and particularly spherical objects equal to or less than 1.75 inches (44.50 mm) in diameter, are especially dangerous. Consumer product legislation should take account of these data.³³ The main risks are to children under three years. In this age group the second molars have not yet developed, the child's grinding and swallowing mechanisms are poor and glottic closure is immature.³⁷

Pharynx and oesophagus

When considering foreign bodies in the pharynx and oesophagus, whether the object is potentially penetrating (sharp or corrosive) or nonpenetrating is probably the most pertinent consideration. The vast majority of swallowed objects pass through the digestive tract and are excreted, often undetected.³⁸ A small (and statistically undeterminable) proportion will impact in the pharynx or oesophagus. There is a clear history of ingestion in 96 percent and the median age was three years in a retrospective ten-year review of 327 patients. Complications, including respiratory symptoms and abscess formation, occurred in 7.6 percent of cases, the latter always associated with sharp foreign bodies and the former more common in the younger age group.³⁸

Management

A plain radiograph will often show the position of the foreign body, provided the child is stable enough to undergo an x-ray. If there is doubt, a lateral view will help to determine if the object is in the pharynx or the airway (Figure 92.3). Bear in mind that an object in the upper oesophagus can cause airway obstruction by pressing on the adjacent trachea. Once the presumptive diagnosis of a pharyngo-oesophageal foreign body has been made, arrangements should be made for early removal as oedema and mucosal swelling will make retrieval more difficult.

The use of rigid angled nasendoscopes and curved forceps designed for fish bone removal has greatly facilitated fish bone removal from the oropharynx under local anaesthetic in adults,³⁹ but general anaesthesia is more likely to be needed in a child. Other original techniques, such as using nasal suction catheters in conjunction with nasendoscopy, have also been described.⁴⁰ Small fish bones may be undetectable and there is some evidence that, even without removal, they may absorb without further sequelae.⁴¹ This fact must not lull the surgeon into a false sense of security as prompt management of all pharyngo-oesophageal foreign bodies results in better outcomes and reduced complications.^{34, 38} Major complications include retropharyngeal and mediastinal abscess, migration of the foreign body into deep structures, oesophageal perforation (from either the

Figure 92.3 (a) Foreign body (coin) in the oesophagus. The lateral view (b) confirms the position.

foreign body or endoscopic procedure) and luminal stenosis.^{34, 42} Again, alkaline batteries are particularly dangerous because the tissue necrosis can be devastating and fatalities have been described.⁴³

For oesophageal foreign bodies the choice between flexible and rigid endoscopy remains controversial.³⁴ Rigid endoscopy is historically associated with a perforation rate of 0.2–1.2 percent compared to rates of 0.02–0.05 percent with flexible endoscopy;³⁴ however, in retrospective series looking specifically at endoscopy for foreign body removal, no difference in complication rates was found.³⁸ Rigid endoscopy gives a much better view of the hypopharynx, cricopharyngeus and the first few centimetres of the cervical oesophagus, whereas a flexible endoscope gives an excellent view in the thoracic oesophagus and oesophago-gastric junction.³⁴

In a review of 5240 patients with ingested foreign bodies from Hong Kong, a management algorithm with flexible oesophagoscopy only used for patients (of all ages) with symptoms distal to the sternal notch resulted in 7.7 percent requiring rigid pharyngo-oesophagoscopy and 1.5 percent having flexible endoscopy (with over 90 percent of patients being managed conservatively). Complications from the foreign body or endoscopy occurred in 0.6 percent.³⁴

The delicate structures of the oesophagus in the child mean that instrumental perforation of the pharynx or oesophagus is an ever-present danger. For the investigation and management of suspected perforation of the oesophagus the reader is referred to Chapter 156, Oesophageal diseases.

Larynx

Glottic impaction of a foreign body often leads to laryngospasm and sudden complete airway obstruction and death with peak incidence at one to three years.⁴⁴

Large, thin objects, such as artificial nails,⁴⁵ may be more prone to lodge in the larynx and indeed in almost all cases of successful surgical removal of a foreign body, the object is small and thin.⁴⁶ Larger objects are either removed by emergency clearing procedures or else death is rapid, unless a surgical airway is created within seconds.⁴⁶ It has been estimated that in the 1970s, almost 600 children per year died in the USA from airway obstruction.⁴⁷ However, public education and awareness of first-aid procedures for acute foreign-body ingestion into the airway has resulted in a nine-fold reduction in mortality rates. The 'Heimlich manoeuvre', which involves compression of the upper abdomen to encourage expulsion of a foreign body, was introduced in 1975.⁴⁸ In infants, lying the child on its back on the adults knee and pressing firmly on the upper abdomen (Figure 92.4) is the preferred manoeuvre. In recent years, audit has shown that 85 percent of airways are cleared before emergency teams arrive, with 38 percent being cleared by the children themselves.⁴⁹

Younger children are less likely to clear their own airway. Emergency practitioners use this fact to argue for the widespread teaching of airway-clearing manoeuvres to new parents.⁴⁹ Older methods previously taught for airway-clearing, such as 'finger-sweeping' can in fact result in the subglottic impaction of foreign bodies and are no longer recommended.⁵⁰ [*//*][Grade C/D]

If the history is at all suggestive of an inhaled foreign body in a child, even if examination is normal, seek the advice of an experienced otolaryngologist.

Tracheo-bronchial tree

The peak incidence of inhaled foreign bodies is between the ages of one and three years, with a male:female ratio of 2:1.^{49, 51} Only 12 percent will impact in the larynx with most passing through the cords into the tracheobronchial tree.⁵² In contrast to adults, where objects tend to lodge in the distal bronchi or right main bronchus, in children they tend to lie more centrally within the trachea (53 percent) or just distal to the carina (47 percent).^{53, 54}

The typical history is of a choking episode while the child feeds or while (s)he is playing with a toy or small object. Vigorous coughing ensues. The parents then find to their alarm that the object has disappeared. This can be followed by a relatively symptom-free period as the object lodges in the lower airway. Partial obstruction of one of the main stem bronchi causes the characteristic wheeze over one side of the chest on auscultation and the hyperinflation of one lung evident on chest x-ray, although these classical findings are by no means universal. The hyperinflation occurs due to a 'ball-valve' effect where the negative intrathoracic pressure on inspiration dilates the bronchial lumen around the foreign body. Upon expiration, the positive pulmonary pressure compresses the main bronchi, occluding the airway around the offending object, preventing expulsion of the air.

Although most patients present with a history of wheeze or cough, up to 20 percent may present after several days due to secondary respiratory complications.⁵¹ A high index of suspicion and early consideration of bronchoscopy are essential. If the child is well enough, a plain chest x-ray may show the characteristic changes of 'obstructive emphysema' as air is trapped beyond a partly occluded bronchus (Figure 92.5). The use of CT to aid diagnosis of tracheo-bronchial foreign bodies has not been a great advantage. Peanuts do not show up well (sensitivity of <35 percent), although objects such as LEGO™ can be detected easily with a sensitivity and specificity in excess of 90 percent.⁵⁵

Better public awareness of the dangers of small objects and legislation to control their use in toys and household objects has meant that in western communities even highly specialized otolaryngologists in large tertiary institutions such as Johns Hopkins Hospital may only see an average of 5.9 cases per year. Residents may only

Figure 92.4 Emergency manoeuvres to encourage expectoration of a laryngeal foreign body in children: (a) back blows to an infant; (b) abdominal thrusts to an infant; (c) back blows to a small child; (d) Heimlich manoeuvre in a standing child. Redrawn with permission from Mackway-Jones K (ed). 2004. *Advanced paediatric life support: the practical approach*, 4th edn. London: BMJ Books.

see or perform between one and eight cases during their training.⁵⁶ Teaching on animal models and/or manikins is mandatory for trainees to develop the skills required to cope with this most difficult airway emergency in a particularly vulnerable patient population.

If the foreign body goes untreated, mediastinal shift, pneumothorax or pneumonia are common sequelae. Smaller foreign bodies may induce granuloma formation and an aggressive search for the foreign body must be made in new cases of bronchial granuloma.⁵⁷ If a foreign body is left untreated for many years, lung resection for bronchiectasis may eventually be required.⁵⁸

In the acute situation, whilst emergency preparations for surgical removal are underway, high flow oxygen is essential and a helium-oxygen mixture (Heliox®) may help reduce the work of breathing.⁵⁹ Even after successful removal, atelectasis, pneumonia, retained fragments, airway spasm or airway oedema may still occur and the child should be monitored closely,⁵⁶ ideally in a high-dependency or intensive-care facility.

Once a foreign body is removed, a meticulous examination of the tracheobronchial tree must be undertaken to exclude further foreign bodies/fragments or other abnormalities.^{60, 61} Following rigid bronchoscopy,

Figure 92.5 Chest x-ray showing hyperinflation of the right lung due to a foreign body in the right main stem bronchus.

some institutions use systemic steroids and nebulized vasoconstrictors to reduce airway oedema and the incidence of postoperative complications.

In a series of 250 patients with tracheobronchial foreign bodies, there was a clear history of ingestion in only 38 percent of cases and over 99 percent of cases were successfully treated endoscopically.⁶² In 95 percent of patients in one series, a history of choking, coughing or wheeze was present. When bronchoscopy was performed, foreign bodies were identified and removed in 80 percent of cases.⁶³ However, in a series of 235 cases, the sensitivity of choking and coughing (82 and 80 percent) was high. The sensitivity of a chest radiograph was 66 percent with a specificity of 51 percent. The sensitivity of auscultation was 80 percent with a specificity of 72 percent. The combination of history, signs and radiological abnormalities is more useful than any one separately and a high index of suspicion is essential.⁶⁴ In a large series of 500 patients, the mortality rate in 1977 was 1.8 percent,⁶⁵ but in a more recent large series the mortality was only 0.8 percent.³⁵

The choice of either using a flexible or rigid endoscope remains controversial. Otolaryngologists traditionally believe rigid endoscopes to be the optimal instrument for tracheo-bronchial foreign bodies.⁶⁶ The airway is controlled, there is a large spectrum of sizes and instrumentation available, excellent visualization via rigid optical endoscopes and the ability to use the scope itself as a conduit for removal of the foreign body.⁶¹ However, there are certain objects that may be more suitably removed with flexible fiberoptic instruments, or a combination of rigid and flexible techniques.⁶⁷ In one series of 26 patients (including two where rigid endoscopy had failed due to the distal location of the objects), using ureteral stone baskets and forceps, flexible bronchoscopy

was able to remove 100 percent of objects.⁶¹ In most cases, the airway was secured via an endotracheal tube or laryngeal mask, although in the cases of failed rigid endoscopy, the rigid scope served as the conduit for the flexible instrument.⁶¹ Where standard 3.6-mm paediatric flexible bronchoscopes are used, the biopsy channel can be used for instrumentation, but if the ultrathin (2.2 mm) scope is used in smaller children, baskets and forceps need to be passed down the side of the flexible scope.⁶¹ Bleeding may occur during the removal of a foreign body, but this can usually be controlled using adrenaline-soaked balls or patties.⁶¹ [*//*]

The standard paediatric flexible scope requires an endotracheal tube with a minimum internal diameter of 4.5 mm. Even then, delicate instrumentation may be impossible without periods of apnoea. As is often the case in medicine, the decision to use flexible or rigid

instrumentation depends on a variety of things, including the availability of equipment, experience of personnel, the age and medical status of the child, nature of the object and length of time since impaction. Ideally, a coordinated team of surgeons and physicians, trained in both rigid and flexible endoscopy, who can perform the removal of the foreign body in one procedure undertake this work and accept patients from a designated catchment area.⁶¹ Skilled paediatric anaesthesia is vital and close cooperation between the anaesthetist and bronchoscopist is essential to ensure the child's alveolar ventilation is maintained throughout the procedure.

The newer optical grabbing forceps contain an integrated telescope and can be passed through most rigid ventilating bronchoscopes (size 3.5 and above). They give a superb view of the trachea and the main stem bronchi (Figure 92.6). This enables the operator to grasp an object such as a peanut under direct vision. These optical instruments have made the management of tracheobronchial foreign bodies much easier and safer, although not all institutions have such instrumentation. Fogarty catheters and other improvised equipment can be used to successfully extract bronchial foreign bodies⁶⁸ although, even in experienced centres, a small percentage of cases (1.8 percent in one large series)³⁵ will need thoracotomy to remove the foreign body and extra-corporeal membrane oxygenation can be used to 'buy time' and prevent mediastinal compression in extreme circumstances.⁶⁹

KEY POINTS

- 'Button' batteries are potentially corrosive. Whether in the ear canal, the nose or the aerodigestive tract they should be removed as soon as possible.
- Instrumental perforation is an ever present danger when removing oesophageal foreign bodies in children.
- Bronchoscopy for foreign body extraction is a highly skilled technique. Teaching and learning this skill is difficult in communities where foreign body aspiration is now rare.
- A high index of suspicion is essential in suspected foreign body inhalation in children. This is a potentially lethal condition.

Best clinical practice

- ✓ Spherical objects, items in the deep meatus and foreign bodies present for over 24 hours are more likely to require a general anaesthetic for removal. [Grade B]

- ✓ Multiple, ill-prepared attempts at removal should be avoided. Early referral to an otolaryngologist must be considered if there is any doubt as to the success of an extraction attempt. [Grade C]
- ✓ Otomicroscopy, micro-instruments, suction, irrigation, glue-tipped probes and open surgery all have their place. [Grade B]
- ✓ Ninety-five percent ethanol is most effective for killing lodged insects prior to their removal. [Grade B]
- ✓ If general anaesthesia is required, it is reasonable to wait for a suitable elective operating list, except for corrosive items and live animals/insects which require urgent removal. [Grade C]
- ✓ Once the presumptive diagnosis of a pharyngo-oesophageal foreign body has been made, arrangements should be made for early removal as oedema and mucosal swelling will make retrieval more difficult. [Grade C]
- ✓ If the history is at all suggestive of an inhaled foreign body in a child, even if examination is normal, seek the advice of an experienced otolaryngologist. [Grade C/D]

Deficiencies in current knowledge and areas for future research

- A global campaign focussing on consumer legislation to monitor the size of small objects, toys and household goods would greatly reduce mortality from inhaled foreign bodies in children.
- Increased parent and carer awareness of the dangers of small objects which children can swallow or inhale should also help reduce mortality.
- Re-organization of otolaryngology services and restructuring of training in ORL needs to take account of the need for centralized and skilled care for the removal of inhaled foreign bodies in children.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words tracheostomy and child. The author has a personal bibliography of key papers on tracheostomy in children.

INTRODUCTION AND HISTORICAL PERSPECTIVE

Widely acknowledged as one of the oldest documented surgical procedures, detailed historical accounts of tracheostomy are many and vivid. Widespread use of the procedure in children developed in the nineteenth century after Trousseau used the technique to relieve airway obstruction in diphtheria. Subsequently, the procedure was widely used in the treatment of poliomyelitis. With the introduction of widespread vaccination programmes these diseases have largely disappeared in the Western world.

Until the late 1970s many tracheostomies in children were performed to relieve airway obstruction in acute airway infections such as epiglottitis and acute laryngo-tracheobronchitis (ALTB or croup, see Chapter 87, Acute laryngeal infections).^{1,2,3} As the standard of paediatric intensive care facilities improved and prolonged endotracheal intubation became a practical alternative to surgical tracheostomy, progressively fewer procedures were carried out for these indications. By the time

haemophilus influenza B (HiB) vaccine was introduced in the 1990s, endotracheal intubation rather than tracheostomy had become the accepted mode of airway management for acute bacterial epiglottitis.⁴

In a series of 153 paediatric tracheostomies, Line *et al.*² report that prior to 1980, 38 percent of tracheostomies were performed for acute airway infections whereas after 1980 this figure had dropped to 12 percent. Similar findings were reported by Friedberg and Morrison⁵ when comparing a series of tracheostomies from 1981 to 1985 to a similar series from the same institution from 1976 to 1980. Crysdale *et al.*⁶ also report an overall reduction by half in the incidence of tracheostomy in the same period, attributed to the change in management of epiglottitis. Corbett⁷ reviewed 116 cases over a ten-year period (1995–2004) and reported a further shift in indications with no tracheostomies for acute airway infections alone and an increasing proportion required for congenital defects such as craniofacial anomalies and major upper gastrointestinal defects. Eighteen children (15.5 percent) required tracheostomy for acquired airway lesions

including subglottic stenosis, vocal cord palsy and respiratory papillomatosis, whilst 14 (12.1 percent) tracheostomies were to facilitate management of airway malacia (laryngotracheal, bronchial or a combination). Tracheostomy was also required for long-term ventilation in patients with neuromuscular disorders (14, 12.1 percent) or ventilator dependency (31, 26.7 percent).

Tracheostomy in children is now an uncommon operation. Due to a shift in tertiary paediatric treatment to larger centres in the last decade and the lack of a reliable means of collecting data on a national basis, it is difficult to estimate the true incidence of paediatric tracheostomy. A survey of 2065 tracheostomies across the United States estimates a rate of 6.6 tracheostomies per 100,000 child years, with the highest incidence in the first year of life but with a second peak in incidence in the late teens due to increased risk of serious injury and trauma.⁸

A more recent study of indications in 362 tracheostomies between 1993 and 2001 has found no real change in incidence over the last decade.⁹

As a consequence of the relative scarcity of the procedure, the medical literature relating to paediatric tracheostomy is generally related to levels 3 and 4 evidence. There are no significant randomized controlled trials and the majority of publications tend to document the authors' own series of tracheostomies and their complications in larger children's hospitals. Reports of changing indications from such institutions may also be skewed by changes in medical practice in individual units.

INDICATIONS FOR PAEDIATRIC TRACHEOSTOMY

The general indications for tracheostomy are as follows:

- relieve upper airway obstruction;
- prevent complications of prolonged intubation;
- reduce anatomical dead space;
- allow suction toilet of the trachea.

However, in practice, tracheostomies in children are nearly always performed to relieve upper airway obstruction or to allow or assist with mechanical ventilation.

Obstruction of the upper airway

The upper airway (from the lips and anterior nares to the carina) may become obstructed at one or more anatomical levels by a range of pathologies (Table 93.1). If the obstruction is significant and life-threatening and no other means of relieving the obstruction (for example, nasopharyngeal airway or prong) is appropriate then a tracheostomy must be considered.

Increasing availability and standard of paediatric intensive care facilities has allowed surgical procedures involving the airway to be undertaken without the need

Table 93.1 Examples of obstruction of the upper airway potentially requiring tracheostomy.

Anatomical site	Example
Oropharynx, tongue base	Macroglossia Treacher Collins/Goldenhar syndrome Cystic hygroma
Nose, nasopharynx	Choanal atresia
Supraglottis	Supraglottic cyst
Glottis	Vocal cord palsy Physical trauma
Subglottis	Subglottic stenosis, haemangioma
Trachea	Tracheomalacia High tracheal stenosis

for a covering tracheostomy. Instead, the risk of postoperative airway obstruction is avoided by a period of intubation and ventilation (the 'single stage' approach).

The relative indications for tracheostomy continue to change. As an example, until the late 1990s, tracheostomy was considered the mainstay of management for obstructing subglottic haemangioma. More recently, tracheostomy is often avoided by open excision.¹⁰ Similarly, the introduction of the cricoid split¹¹ and single stage laryngotracheal reconstruction¹² can avoid the need for tracheostomy for extubation failure due to subglottic oedema. [**]

Prolonged intubation

The long-term complications of prolonged endotracheal intubation are well recognized – ulceration at the level of the glottis and, particularly in children, the subglottis, can lead to cicatrization and stenosis of the airway. [****] Being softer and more flexible than the adult and with correct selection of tube size and appropriate intensive care, the neonatal larynx is able to tolerate prolonged intubation for relatively longer than the adult.

There is no clear consensus as to the maximum safe duration of intubation. Premature babies may now be intubated for several weeks before permanent damage becomes a risk. Although practice varies in different units, tracheostomy should normally be considered in older children after two to three weeks of endotracheal intubation.

Long-term and home ventilation

An increasing number of children are now surviving previously lethal conditions, resulting in chronic respiratory failure because of the availability of long-term ventilation. Around half of these are ventilated by

tracheostomy.¹³ Indications for long-term ventilation include:

- failure of control of breathing;
- chest wall dysfunction;
- disorders of lung parenchyma;
- large airway disease;
- central sleep apnoea, Ondine's curse;
- thoracic dystrophy;
- bronchopulmonary dysplasia (BPD);
- tracheobronchomalacia.¹⁴

Increasingly, these patients can be ventilated at home although the cost in terms of manpower and equipment is high.

Tracheal toilet

In practice, very few children now require tracheostomy for toilet of the airway. Children with intractable aspiration may need regular suction but the presence of a tracheostomy can predispose to aspiration in itself and increase the risk of respiratory tract infection.

TECHNIQUES OF TRACHEOSTOMY SPECIFIC TO CHILDREN

Positioning

The infant is positioned supine on the operating table. Neck extension is achieved with a rolled towel or gel pillow under the shoulders. The neck can be fixed in extension and stabilized in the midline using adhesive tape such as Elastoplast®. (Figure 93.1) Theoretically, extension of the neck in infants increases the risk of injury to the great vessels in the root of the anterior neck; in practice, with careful dissection and identification of structures this is rarely a clinical problem.

Figure 93.1 Child positioned on the operating table for tracheostomy.

Skin incision

The conventionally used skin incision is horizontal, situated halfway between the cricoid and sternal notch. A vertical incision has traditionally been less favoured because of the potentially poorer cosmetic outcome, but after decannulation from a long-standing tracheostomy, the resulting scar is such that it is unlikely that the orientation of the original incision will make much difference. An advantage of a vertical incision is that it facilitates midline dissection through the layers of the neck and is therefore sometimes advocated as the incision of choice in emergency tracheostomy.

The subcutaneous fat immediately surrounding the incision may be removed after completing the skin incision. This allows the skin edges to invert slightly so as to line the tracheostome with squamous epithelium. This effect can be increased by suturing the edge of the skin incision to the edge of the tracheal incision (maturation sutures). The resulting tract is felt to be more secure as it is already lined with squamous epithelium, and may be associated with a lower rate of postoperative complications.¹⁵

Dissection

Dissection using monopolar or bipolar diathermy is advisable in small children to minimize blood loss. Although in adults and larger children the thyroid isthmus is traditionally divided and tied to prevent haemorrhage, in infants it is usually adequate to divide the isthmus of the thyroid with bipolar diathermy.

Given the relatively small size of the infant neck and trachea, and secondly the relative proximity of the carotid sheath, it is advisable to palpate the trachea regularly throughout the dissection to ensure that the direction of dissection has not strayed from the midline.

Tracheal incision

A vertical incision is made in the midline, usually in tracheal rings 3–4. It has long been established that too high an incision in the trachea predisposes to subglottic stenosis.¹⁶ A variety of other incisions has been advocated, including excision of an anterior tracheal window, a superiorly or inferiorly based tracheal flap which is raised and sutured to the skin or, recently, a cruciate incision in the trachea, the tracheal edges being closely apposed to the skin edges.¹⁷ The theoretical advantage of most of these techniques is increased stability of the initial tracheostomy tract and therefore greater safety in the event of accidental decannulation. However, although there is no evidence available from randomized clinical trials, animal experiments¹⁸ suggest that tracheal flaps may lead to an

increased risk of long-term stenosis and the majority of authors currently favour a simple vertical incision. [**]

Stay sutures

Stay sutures are placed in the wall of the trachea on either side of the vertical incision. These are generally a removable suture (e.g. 4/0 PROLENE) and are left *in situ* until the first tube change. In the event of accidental decannulation, upward and lateral traction on the sutures will open the tracheostomy to make tube reinsertion simpler. The sutures may be taped to the chest wall (Figure 93.2) to prevent accidental removal.

Securing tracheostomy tubes

Until the tracheostome has epithelialized and matured, the risks associated with accidental decannulation are more significant. Initially, it is the author's practice to fix the tube into position in the neck using the inelastic linen tapes supplied with the tube. The tapes are tied in a secure knot, sufficiently tight to allow one finger to be inserted between the tapes and the neck skin (Figure 93.3). The tapes should be tightened with the neck flexed, rather than

© Hodder Arnold / Scott-Brown 7E

Figure 93.2 Stay sutures in place.

© Hodder Arnold / Scott-Brown 7E

Figure 93.3 Securing the tapes.

in the operative position with the neck extended. In the author's view, suturing the flange of the tracheostomy tube to the skin should be avoided in children. After seven days the first change is undertaken and the linen tapes may be changed for a Velcro® fastening which allows for easier changing and is less traumatic to the skin of the neck.

TRACHEOSTOMY CARE

Adequate tracheostomy care is critical in the first two to three postoperative days. It is during the formation of the tract of the stoma that the risk of tube displacement is at its highest as the tract can close very quickly making reinsertion difficult. It is difficult to overstate the importance of tracheostomy nursing care in the post-operative period. With meticulous and skilled care, most of the complications of tracheostomy can be avoided. Inexperienced staff with no specific training are often reluctant to intervene. It is therefore essential that hospitals maintain a high standard of internal training in this regard and many units have specific teams and regular training programmes for nursing staff.

Suction

Immediately after tracheostomy, the change from air that is warmed and humidified by the upper airway to dry cold air leads to a rapid increase in airway secretions. This gradually reduces after a few weeks. Secretions dry on the inside of the tracheostomy tube and gradually reduce the effective lumen. Humidification of inspired air and regular suctioning will reduce this tendency. Suctioning is required as often as is necessary to keep the tube and airway clear. Overzealous suctioning may lead to mucosal trauma in the distal trachea if the catheter is inserted into the tracheal lumen itself¹⁹ and eventually granulation may form at the tip of the tracheostomy tube, which in itself may lead to tube obstruction. It is suggested that the suction tube be inserted as far as the tip of the tracheostomy tube and withdrawn with a finger occluding the side port. The exact distance may be measured and marked on the suction tube.

The need for suctioning decreases in frequency over time, although with lower respiratory tract infections, secretions may become thicker and more profuse. On such occasions, irrigation of the tracheostomy tube with sterile saline to loosen secretions prior to suctioning is often advocated but there is little evidence to support this practice and it may increase contamination of the lower airway.²⁰

Humidification

Initially humidification should be given via nebulizers and a tracheostomy mask (Figure 93.4). After a week or so, secretions reduce and the level of humidification

Figure 93.4 Tracheal mask for humidification.

Figure 93.5 Swedish nose.

required is less. A few weeks after tracheostomy, more mobile devices can replace permanent humidification. Longer-term humidification may be achieved by using a Swedish nose or a tracheostomy bib. A 'Swedish nose' attachment (Figure 93.5) contains a filter which becomes saturated by the moisture in exhaled air; this in turn humidifies the inhaled air. The tracheal bib works in a similar way. Both devices have the advantage of acting as filters for inspired air.

Skin care

The tracheostomy wound itself becomes rapidly infected with skin commensals and is impossible to keep sterile. The wound heals by secondary intention and eventually the tract becomes lined with squamous epithelium and organized scar tissue. Securing the wound edge skin to the trachea with maturation sutures hastens the development

of an epithelialized tract. At this stage the tracheostome is considered mature. Until this point there is usually a considerable discharge from the wound itself and if the skin care in the first few days is not meticulous, skin and wound breakdown will occur. Usually a dry gauze or foam (e.g. Lyofoam®) dressing is inserted between the peritracheostomy skin and the flange of the tube. This is rapidly saturated and needs to be changed regularly. Of course the action of changing the dressing increases the risk of accidental decannulation and there is often reluctance on the part of nursing staff to do this. Adequate training in tracheostomy care is essential in a hospital where regular paediatric airway surgery takes place.

Large skin incisions are generally not required in paediatric tracheostomy. If not adequately closed, a large incision will lead to gaping and wound breakdown. It is futile to attempt closure in this instance because of the bacterial colonization of the wound and inevitable infection. Large tracheostomy wounds require careful dressing and packing similar to a healing ulcer and a range of wound products are available. The wound will eventually close by secondary intention.

The tapes used to secure the tube in place can lead to ulceration of the neck skin if they are left too tight or for too long. Although the linen tapes supplied with tubes are secure and inelastic, they have a tendency to cut into the skin. Again, meticulous nursing and skin care is vital. The problem can be reduced by tying the tapes inside a sleeve of Tubigrip™ or part of a large plastic (e.g. endotracheal) tube. When the tracheostomy matures, wider softer bands with Velcro fittings may be used and are less traumatic to the neck skin.

Change of tracheostomy tube

The first change of tube is generally undertaken at around the seventh postoperative day. This allows some time for maturation of the stoma but is short enough to reduce the risk of tube obstruction from dried and thickened secretions. The first change should be undertaken by an otolaryngologist; in the relatively rare instance of difficulty reinserting the second tube, an emergency surgical procedure may be required.

If oral intubation is difficult or impossible (e.g. retrognathia, laryngeal stenosis) it is advisable to undertake the first change in the operating theatre in case surgical intervention is needed. In children who can be easily intubated, (for example the majority of children tracheostomized for prolonged ventilation), it is more usual to undertake the first change on the intensive care unit, with an intubation trolley and senior ITU medical staff on hand should reinsertion be difficult and reintubation required.

If this procedure is uneventful, the nursing staff can carry out subsequent changes. If discharge home is

anticipated, the parents must be taught the tube-changing technique in a secure environment.

There is no standard proscribed interval at which tubes should be changed; this varies between children and also in the same child given variation in season and in the health of the lower airway. The tube needs to be changed before dried secretions start to reduce the lumen of the tube. The old tube should be inspected after removal to determine the degree of contamination and this will influence the interval until the next change. If a tube visibly contains dried secretion on external inspection, has an audible whistle due to obstruction ('if you can hear a tube you should change it') or if the suction catheter cannot be passed due to obstruction, then it should be changed. If the suction catheter does not pass freely after changing the tube, the advice of an otolaryngologist should be sought.

TYPES OF TRACHEOSTOMY TUBE

Diameter

Modern tracheostomy tubes are sized in relation to the diameter of the lumen in millimetres. Older tubes still use the French gauge system of sizing. The age-appropriate size for a tracheostomy tube can be derived from the guide shown in **Figure 93.6**. In general terms, smaller sized tubes become obstructed more easily and may impair respiration if too small for the age of the child. A child with a long-standing tracheostomy should undergo regular age-appropriate 'upsizing'. However, tracheostomy tubes tend to almost completely fill the trachea in very young children making normal speech difficult. In some cases, for example, if the airway above the tracheostome is not completely obstructed, a smaller sized tube will allow air to flow up through the glottis and aid in normal speech production. Too large a tube will predispose to suprastomal collapse and may increase the risk of granulations and stenosis.

Length

When inserted correctly, the end of the tracheostomy tube should sit comfortably proximal to the carina. Too long a tube will abut the carina and lead to mucosal injury and potentially subsequent scarring. Too short a tube increases the risk of accidental decannulation. Ideally, the tube should be at least 2 cm, inside the stoma and 1–2 cm, clear of the carina.²¹

Shiley® and Bivona® tubes commonly in use in the UK are available in neonatal and paediatric lengths. For unusual applications (for example children with very thick necks), tubes with adjustable lengths are available (**Figure 93.7**). Tube tip position can be assessed on chest

x-ray, at regular rigid bronchoscopy or by passing a flexible endoscope down the lumen of the tube to inspect the carina.

Material

Silicone is now the most widely used material in paediatric tracheostomy tubes. Their relative flexibility compared to older metal tubes reduces the risk of mucosal trauma during neck movements and the soft flange is less likely to lead to skin injury around the tracheostome. One advantage of metal tubes is that as the stronger metal wall is thinner, it is possible to achieve a smaller outside diameter for the same internal diameter as a silicone tube.

Speaking valve

Speaking valves are one-way valves which allow inhalation through the tube but force air upwards through the glottis on exhalation, creating sufficient subglottic pressure to allow phonation. As well as allowing speech, by increasing tracheal pressure on exhalation, these may improve lung function and reduce aspiration. Speaking valves should be used under supervision and not while the child is asleep. Small infants will not always tolerate the valve and quickly learn to blow the valve off the tracheostomy by coughing hard. Many children learn to occlude the end of the tube on exhalation by flexing the neck and occluding the end of the tube with the neck skin to achieve the same result to help phonation.

Fenestration

Fenestrated tubes allow air to pass upwards to improve phonation. These are less practical in smaller children as the fenestration tends to become a focus for granulation and mucosal trauma on suctioning. Adequate passage of air upwards into the larynx is usually achieved by selecting a smaller tube diameter and allowing air leakage on expiration.

Inner tube

For a tube of any given outer diameter, an inner tube will substantially reduce the diameter of the lumen and is therefore not practical in smaller children. For older children, tubes are available with inner tubes in silicone or metal. The main advantage is that the inner tube can be removed daily for cleaning; secondly, the inner tubes are often available with an integrated speaking valve.

Figure 93.6 Chart for sizing tracheostomy tubes. Reproduced with kind permission from Michelle Wyatt and colleagues at the Department of Otolaryngology, Great Ormond Street Hospital, London, UK.

Cuff

The presence of a cuff increases the risk of mucosal ischaemia and subsequent tracheal stenosis, particularly if high cuff pressures are employed. Cuffed tubes are rarely indicated in paediatric practice; until adolescence, a sufficient seal to allow positive pressure ventilation can normally be achieved with an uncuffed tube.

There are two specific indications for cuffed tubes in children: firstly where there is a significant risk of aspiration (although a cuff will not completely protect against this) and secondly, where there is a decrease in lung compliance with intercurrent infection in a ventilated child and ventilation pressures need to be raised temporarily. In this instance, the risk of tension pneumothorax is significantly increased. In the author's institution, children on the home ventilation programme are admitted to hospital for observation if the ventilation pressures become high enough to require a cuffed tube.

Variable/custom-fitted tubes

The Bivona® Hyperflex™ tube has an adjustable flange which allows change of the effective length of the tracheostomy tube (Figure 93.7). This is useful in

© Hodder Arnold / Scott-Brown 7E

Figure 93.7 Bivona® adjustable tube.

children with prominent soft tissue in whom the prominent neck tissue would obstruct a normal tracheostomy tube, and in children in whom a low tracheal obstruction needs to be bypassed by the tube. The disadvantages of this sort of tube are that it is firstly expensive and secondly, the wall of the tube is thick resulting in a relatively small tube lumen. Custom-made tubes are available for children with specific anatomical difficulties. Tube manufacturers should be approached directly for advice.

COMPLICATIONS OF TRACHEOSTOMY

General

Tracheostomy complications are more likely in children than in adults, and more common in children under two years,^{1, 22, 23} particularly preterm infants.²⁴ [**] Overall complication rates are quoted between 25 percent²⁵ and 77 percent.²⁶ There is likely to be considerable variation in the documentation and reporting of minor complications – some authors do not consider granulation to be a reportable complication (Table 93.2).

The higher complication rate in smaller children is likely to reflect the relatively small diameter of the airway in small children and the ease with which the airway may be occluded (for example by secretions, granuloma or suprastomal collapse), but also the fact that younger children receiving tracheostomy may remain tracheostomized for a longer period.²⁶

As with adult tracheostomies, emergency procedures are associated with a higher rate of complications²⁷ and longer duration of tracheostomy is associated with a higher risk of long-term complications.²⁸ Given the relative scarcity of paediatric tracheostomy and the limited number of large published series, it is difficult to accurately derive a risk for fatal complications of paediatric tracheostomy. Of larger studies reported since 1980, the mortality related to the tracheostomy tube itself ranges from 0 to 3.6 percent (Table 93.3).^{25, 29} In nearly all cases, the cause of tracheostomy-related death is tube

Table 93.2 Complications of tracheostomy.

General	Early postoperative (up to one week)	Late postoperative (after one week)

obstruction or accidental decannulation. Earlier reports quote higher mortality rates but paediatric otolaryngology practice has changed considerably in the last 30 years and older studies are unlikely to reflect current practice and safety. Mortality from nontracheostomy-related medical conditions, such as respiratory or cardiovascular disease, is consistently high (7–36 percent) in all series,^{23, 27} reflecting the complex medical conditions of children requiring tracheostomy.

Accidental decannulation

If there is little or no natural airway above the tracheostomy or if a child is ventilator dependent, accidental decannulation can be fatal. The risk is increased by insufficiently tight ties, too short a tracheostomy tube and excessive traction on the tube from ventilator tubing. In the first few days before the tract matures, it is likely to be harder to reintroduce the tube if decannulated. Wetmore *et al.*¹ report accidental decannulation in 29 of 420 (6.9 percent) children in the first week.

The risk of accidental decannulation may be reduced by meticulous tracheostomy nursing care, and surgical techniques (stay sutures, maturation sutures) may help reduce the morbidity by allowing easier and safer reinsertion of a displaced tube.

Tube obstruction

Immediately after tracheostomy the tube is most likely to become blocked with secretions. Regular suction is required. Humidification reduces the rate of secretion and helps to prevent the secretions drying in the lumen of the tube and narrowing the airway. In a mature tracheostomy, the tube is more likely to be obstructed by granulation as the tube tip, either as a result of use of suction catheters or direct trauma from the tube itself.

In the event of accidental decannulation, the tube should be reintroduced in a controlled manner to prevent the creation of a false passage.

Pneumothorax, pneumomediastinum, surgical emphysema

In the infant the domes of the pleura extend well into the neck. Inadvertently straying from the midline during dissection increases the risk of postoperative pneumothorax. This should be detected immediately postoperatively on a routine chest x-ray. Small pneumothoraces can be treated conservatively while larger ones will require chest drainage.

If the tracheostomy wound is closed too tightly around the tube, or the dressings are too tightly applied to the neck skin, air may leak into the soft tissues of the neck

(surgical emphysema) or track down into the mediastinum. In this instance the wound should be reopened to allow air to track back out through the tissues and a corrugated drain should be inserted.

Bleeding

Bleeding in the first few days after tracheostomy usually arises as a result of failure to achieve complete haemostasis during surgery. Commonly, bleeding may persist from the wound edge, anterior jugular veins or their tributaries, or the edge of the thyroid isthmus. If direct pressure is not adequate to control haemorrhage, the wound may be carefully packed with haemostatic gauze (Surgicel or Kaltostat®). Re-exploration is rarely required.

Later, minor bleeding may arise from areas of granulation around the tube. This can normally be controlled with cautery and ongoing medical treatment such as application of steroid and antibiotic ointment (for example, Triadcortyl™).

Tracheal innominate fistula

Tracheoinnominate artery fistula is a rare but lethal complication. There is no reliable estimate of the risk in children, which in adults has been estimated as 0.4 percent.³¹

In some children the innominate artery lies abnormally high in the neck (Figure 93.8). If this finding is made at the time of surgery, the decision to perform a tracheostomy should be reconsidered. If there is no safe alternative, it is acceptable to place the tracheal incision higher than one would normally advocate and accept the risk of subglottic stenosis. An abnormally low tracheostomy will also increase the risk. A fistula into the artery

© Hodder Arnold / Scott-Brown 7E

Figure 93.8 High innominate artery.

forms as a result of erosion of the arterial wall by direct pressure from the tube.

Although most bleeding coming from the tracheostomy tube itself is likely to represent granulation formation at the tube tip, in all cases the possibility of tracheal innominate artery fistula should be considered. The trachea should be examined by flexible bronchoscopy on the ward or by rigid endoscopy under anaesthesia. If the bleeding appears to arise from the anterior tracheal wall rather than tube tip granulation, the wound must be re-explored immediately, ideally with the assistance of a cardiothoracic surgeon. It may be possible to tamponade the bleeding by using a cuffed tube temporarily and if the laryngeal anatomy permits, endotracheal intubation should be established prior to exploration. The mortality from this complication remains very high.

Granulation

The presence of the tracheostomy tube as a foreign body and the persistent presence of bacterial flora in the tract act as an ongoing stimulus for the formation of granulation tissue. Granulation may form at the skin edge of the tract (peristomal granulation) and inside the trachea itself, both on the anterior wall of the trachea above the tube (suprastomal granulation) and also at the tube tip lower in the trachea. Excessive or overexuberant suctioning can lead to more granulation through mucosal trauma and the tube itself can cause mucosal injury. This is generally more common with more rigid tube designs, particularly the silver³² and PVC designs.

Granulation tissue can pose a number of problems; on the surface, granulations tend to discharge and bleed and, when severe, can lead to difficulty in changing the tube. More modern tubes made from less reactive silicone are more flexible and softer and are felt to reduce the problem both at the skin and inside the trachea.

Peristomal granulations can generally be controlled with steroid/antibiotic preparations (e.g. Triadcortyl ointment). When more severe they may be removed with bipolar diathermy. Caution needs to be exercised when using silver nitrate cautery as the silver nitrate solution can easily enter the trachea itself leading to irritation, coughing and mucosal injury. In the author's unit, this practice is avoided.

Suprastomal granulations are almost universal. In theory, if large they will reduce the lumen of the supraglottic airway above the tube and increase the risks associated with accidental decannulation. Some authors advocate their removal at endoscopy on a regular basis, however, others feel that they are an inevitable consequence of tracheostomy; Rosenfeld and Stool³³ describe granulation in 80 percent of 265 tracheostomies at bronchoscopy and advise against interval endoscopy to remove granulation tissue. At microlaryngoscopy, immediately prior to planned decannulation, all

granulation should be removed to improve the airway. After decannulation and stomal closure, granulation generally resolves spontaneously.

Removal of suprastomal granulation

Suprastomal granulations may if required be removed endoscopically using microlaryngeal instruments, a microdebrider using a Skimmer® or Tru-Cut® blade or by KTP or CO₂ laser. The KTP laser has the advantage of beam delivery using a flexible optic fibre in the relatively limited confines of the subglottis.

Large granulation may be removed using a small spheno-punch inserted into the tracheostome from externally, under endoscopic guidance at microlaryngoscopy.

Suprastomal collapse

Suprastomal collapse is distinct from suprastomal granulation although the two conditions often coexist. For reasons that are not completely understood, the anterior tracheal wall immediately superior to the stoma itself softens and prolapses into the lumen of the subglottic trachea (Figure 93.9). This can significantly reduce the available airway, which in turn increases risks associated with accidental decannulation and also leads to decannulation failure.

Minor collapse may be left, as it will tend to improve after decannulation. More significant collapse will require surgical treatment. The simplest of these involves excision and transfixion of the tracheostomy tract followed by endotracheal intubation for two to three days to support the trachea as the stoma heals.³⁴

The author's preference in mild to moderate suprastomal collapse is to explore the neck, identify the area of suprastomal collapse and pass a suture through the cartilage and around the strap muscles to elevate the

collapsed section. This is carried out with excision and transfixion of the tracheostome skin. Sharp and Hartley³⁵ describe ablation of the collapsed segment with KTP laser and a number of authors have described supporting the collapsed segment with a cartilage graft in more severe collapse.³⁶ The specific procedure will depend on the degree of collapse and the surgeon's personal preference.

Speech development

There is debate about the extent to which tracheostomy affects the development of speech in children. Clearly, normal phonation will be impaired for the duration of a tracheostomy as insufficient subglottic pressure is generated and small infants tend not to tolerate speaking valves well. One difficulty in interpreting such studies is that a significant proportion of tracheostomized children have coexisting developmental abnormalities. If decannulation occurs in the first year to 18 months, before the time at which normal speech patterns begin to develop, the long-term outcome is favourable,³⁷ whereas longer-term tracheostomy may lead to longer-term impairment of speech function.

DISCHARGE AND HOME CARE

Discharge

Getting home with a tracheostomy is a complex and time-consuming process. Not all families will have sufficient support or resources at home to care for children with a tracheostomy. Whilst in hospital, the caregivers must be educated to care for the day-to-day eventualities of tracheostomy, including tube changing and the recognition and initial treatment of complications. Generally, two responsible adults are required for tube change; home tracheostomy care is difficult, but not impossible for single carers.

Children who are included in home ventilation programmes tend to be more carefully supervised and a national protocol for discharge requirements has been formulated.³⁸ Nonventilated tracheostomized children tend to have less structured support. In some areas, specific local organizations are available (e.g. the lifetime service in Avon and Wiltshire). Generally, home care is shared between hospital and primary care district nurses who have little specific training.

With sufficient support and education of teachers and co-workers, tracheostomized children without other significant disabilities can now attend mainstream schooling in the UK, although certain activities must be avoided, particularly swimming, water-based sports and contact sports. The parent and carer support organization Aid for Children with Tracheostomies (ACT) provides a discussion forum, advice and information for caregivers in the UK,³⁹ and caregivers may be given contact details prior to discharge.

Figure 93.9 Suprastomal collapse.

Physical requirements

Tables 93.4 and 93.5 list the resources required for the child with a tracheostomy at home. In the author's experience, the ease with which equipment and accessories can be obtained by caregivers is extremely variable in the community as financial constraints in the delivery of care lead to reluctance to supply regular consumables. Prior to discharge, it is essential to communicate with the child's general practitioner and other primary care workers and establish responsibility for provision of equipment.

Table 93.4 Requirements for children at home with tracheostomy.

Caregivers	Physical	Support
Generally two responsible adults	Home with adequate space, heating, electricity, telephone, access to transport	District nurse Community paediatrician Health visitor General practitioner Hospital-based support Specific community organizations where available

Table 93.5 Equipment requirements for children at home with tracheostomy with and without home ventilation.

Requirements for children without ventilation	Additional requirements for children on home ventilation
Appropriate sized tracheostomy tubes and one a size smaller	Two ventilators/CPAP machines, one of which is portable plus batteries and chargers for use outside the home
Neck ties to hold tube in place	Disposable ventilator circuits
Scissors for emergency tube change to cut neck ties	Humidifier for ventilator circuit and water for inhalation to supply humidifier
Lubricant for inserting tube	Dry circuit for ventilation when outside the home
Sterile saline and syringes for saline suction if required	Heat and moisture exchanger for dry circuit
Tracheostomy dressing if required	Nebulizer
Gauze to clean stoma	CO ₂ monitor
Appropriate sized suction catheters	Rechargeable torch for use at night in the event of a power cut
Heat and moisture exchangers/Swedish noses	Uninterrupted power supply – battery which powers ventilator in the event of a power cut
Speaking valves	Suitable trolley in bedroom for equipment
Gloves – nonsterile for procedures and alcohol gel hand rub	Adequate power sockets in house, particularly child's bedroom
Plastic aprons and protective goggles	Trolley for children with a lot of equipment to transport equipment at nursery/school
Stethoscope	Larger than normal buggy when baby/toddler to transport child and equipment
Two suction machines, one of which must be portable. Most children keep a third machine at school as spare	
Saturation monitor and possibly portable saturation monitor for use outside the home	
Ambu bag	
Oxygen: concentrator if used on a daily basis, cylinders if used less frequently, portable cylinders	

Most of the above needs to be duplicated in a portable set. A battery powered suction machine is essential and if the child is oxygen dependent, portable cylinders. Reprinted from Ref. 40, with permission.

DECANNULATION

Decision to decannulate

Decannulation may be considered when the original condition requiring tracheostomy has improved, however, to make decannulation successful the child must be able to maintain an adequate airway without the tracheostomy in place.

The majority of paediatric tracheostomies are short term, as the natural airway tends to improve with overall

growth of the child or as a result of corrective surgery such as laryngotracheal reconstruction. The decision to decannulate is a complicated one which needs to be taken by a senior clinician after careful discussion with the parents and other relevant health care professionals.

In paediatric otolaryngology practice it is generally considered essential to undertake endoscopic assessment of the airway prior to definitive decannulation.³⁴ Suprastomal collapse and granulation leads to a considerable reduction in the lumen of the subglottic airway in children. Prescott⁴¹ suggested that this was the most common cause of decannulation failure in children, finding significant granulation in 50 and significant suprastomal collapse in 52 of 300 tracheostomies. [**] In addition, vocal cord mobility should be assessed at endoscopy. Granulation may be removed at the time of endoscopy using punch forceps or laser ablation. More significant suprastomal collapse requires KTP laser ablation or reconstructive surgery using cartilage grafting if the collapse is greater than 50 percent.³⁵ If the subglottic airway is deemed satisfactory at endoscopy, the child may then proceed to formal decannulation in the next few days, delaying the risk of reformation of granulation.

One should also consider comorbidity, such as pulmonary or neurological disease, and lastly the need for further surgery; for example, if a child with Treacher Collins syndrome and an indwelling tracheostomy requires further (e.g. mandibular or palatal) surgical procedures one would normally consider delaying decannulation.

Decannulation technique

Removal of a tracheostomy leads to a significant change in the physiology of the upper airway. The dead space is doubled and airway resistance is trebled. With a long-standing tracheostomy, the child may have no memory of mouth and nose breathing and the new sensation may be distressing.

Staged decannulation

To effect these changes more gradually, decannulation protocols have been developed which involve tube ‘downsizing’ and reversible capping (Table 93.6).⁴² To assess whether the child can breathe through the normal anatomical airway, the tube is capped off, either with a button, by taping or by inserting the obturator. However, the tracheostomy tube itself occupies a significant fraction of the tracheal lumen and to try and reduce this effect, the tube size is reduced to a size 3.0 (or size 2.5 in children under 13 months,⁴³ either in stages or in one step. Leaving the small tube *in situ* allows a certain amount of

Table 93.6 Great Ormond Street protocol for ward decannulation.

Day	Procedure
1	Admission, downsize to 3.0 tube
2	Block for 12 hours from 8 am, if successful continue overnight for a further 12 hours
3	Decannulate, occlude stoma with adhesive tape and dressing. Observe on the ward
4	Observe off the ward
5	Discharge

respiration if required and also prevents the tract from closing down, should decannulation fail.

Immediate decannulation

The tracheostomy tube may occupy as much as half of the lumen of the trachea in an infant. If a child can tolerate this degree of obstruction, the airway after decannulation is likely to be more than sufficient. However, some children will not be able to tolerate this degree of tracheal obstruction. In this instance, it may be considered appropriate to simply remove the whole tube and occlude the stoma with a dressing. However, it is vital that this be carried out in a controlled setting (i.e. intensive care) where facilities for intubation are available should decannulation fail and reinsertion of the tracheostomy not be possible. If the nature of the child’s airway obstruction is such that oral intubation is not possible (e.g. some cases of Treacher Collins syndrome) then it is not safe to remove the tube in this manner, and decannulation should be delayed until the child is large enough to tolerate staged decannulation with capping off.

Persistent tracheocutaneous fistula

After decannulation, a fistula may persist between the trachea and skin. This may be small and only lead to problems with discharge of tracheal secretions. A larger fistula may continue to function as an alternative airway.

The incidence of tracheocutaneous fistula (TCF) is between 19 and 42 percent in various series. Certain factors lead to an increased risk: lower age at initial tracheostomy, duration of tracheostomy and, most importantly, persistent obstruction above the level of the stoma (e.g. inadequate reconstruction of subglottic stenosis). There is no clear consensus as to how long a persistent TCF should be allowed to close before considering surgery. Most authors would allow 6–12 months before formal closure.

Closure of TCF

It is essential that the upper airway be reassessed prior to TCF closure to exclude persistent obstruction and tracheal granulation. The persistence of squamous epithelium lining the tracheostome increases the likelihood of a persistent fistula. Simply removing the skin lining the tract and reattempting conventional extubation may lead to satisfactory closure.⁴⁴ More commonly, the tract of the stoma is dissected down to the level of the trachea and closed with transfixion sutures. The strap muscles can then be reapposed to each other, which tends to fill in the cosmetic defect left after conventional decannulation. Lastly, the scarred skin surrounding the tracheostome can be excised in a fusiform incision with horizontal skin closure. This leads to an excellent cosmetic result. It is the author's practice to leave a drain in the wound for 24 hours in case of air leak from the closure, which might otherwise lead to surgical emphysema and pneumomediastinum.

Revision of tracheostomy scar

After conventional decannulation, the tracheostome heals by secondary intention. The resulting scar is usually unsightly (Figure 93.10) and features a pronounced depression at the line of the tract. Older children may become self-conscious and embarrassed about this. Revision of the scar is usually left until the child is over ten years of age, as cosmetic appearances become more important to the child with age and secondly because there is likely to be less further widening of the subsequent scar with age if the procedure is delayed.

Revision of the scar usually involves a fusiform horizontal incision to excise the scarred skin of the tracheostome with wide undermining of surrounding skin to assist in primary closure. The strap muscles should be identified and reapposed in the midline to eliminate the defect in the contour of the neck skin. Deep dermal/platysmal sutures are used to support the wound and then the skin edges are closed meticulously. Flexing the neck makes it easier to close a large skin defect.

KEY POINTS

- Tracheostomies in children are performed in the main to relieve upper airway obstruction or to assist with mechanical ventilation.
- A reduction in the incidence of infections – notably HiB epiglottitis – which cause airway obstruction in children, and improved management of airway pathology by anaesthetists and paediatricians have brought about a change in the indications for tracheostomy.
- Tracheostomy in children is now an uncommon operation.
- Tracheostomy complications are more likely in children than in adults. Preterm infants are at particular risk.
- Suprastomal granulations are almost universal in children.
- Getting home with a tracheostomy is a complex and time-consuming process. Not all families will have sufficient support or resources at home to care for a child with a tracheostomy.

Best clinical practice

- ✓ Endotracheal intubation rather than tracheostomy is the accepted mode of management for acute obstructing airway infection in children. [Grade C/D]
- ✓ Premature babies may be safely intubated for several weeks. Tracheostomy should normally be considered in older children after two to three weeks of endotracheal intubation. [Grade C/D]
- ✓ Large skin incisions are generally not required in paediatric tracheostomy. [Grade C/D]
- ✓ Careful dissection using diathermy is advisable in small children to minimize blood loss. [Grade C/D]
- ✓ Palpate the trachea regularly throughout the dissection to ensure that you have not strayed from the midline. [Grade C/D]
- ✓ A simple vertical incision to open the trachea is associated with the lowest risk of long-term complications. Avoid removing any cartilaginous tissue in children. [Grade C/D]
- ✓ Stay sutures in the wall of the trachea on either side of the vertical incision facilitate reintroduction of the tube in the event of accidental decannulation before a mature track has developed. [Grade C/D]
- ✓ In children who are difficult to intubate (e.g. retrognathia, laryngeal stenosis), it is safer to do the first tube change in the operating theatre in case surgical intervention is needed. [Grade C/D]

- ✓ The small diameter of the child's airway makes suction and humidification especially important as secretions can quickly occlude the airway. [Grade C/D]
- ✓ Tube obstruction or accidental decannulation may be fatal. [Grade C/D]
- ✓ An 'inner tube' reduces the diameter of the lumen and is therefore not practical in small children. [Grade C/D]
- ✓ Fenestrated tubes are impractical in smaller children. The fenestration tends to become a focus for granulation and mucosal trauma on suctioning. [Grade C/D]
- ✓ Cuffed tubes are rarely needed in children. [Grade C/D]
- ✓ Speaking valves should be used under supervision and not while the child is asleep. [Grade C/D]

Deficiencies in current knowledge and areas for future research

- Paediatric tracheostomy is now largely undertaken in specialist paediatric units. It is difficult for otolaryngologists in training to get experience in the management of children with tracheostomies outside of these centres. This trend is likely to increase.
- Research in paediatric airway disorders is focussed on conditions which give rise to the need for tracheostomy, such as laryngotracheal stenosis and major congenital anomalies.
- There is a need to improve training resources and support in primary care and community settings to enable families to look after tracheostomized children at home.

Specific conditions	1212		

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words infection and child, neck, cervical node, cervical adenopathy and focussing on diagnosis and treatment of specific conditions. The Cochrane Library was also consulted.

INTRODUCTION

Neck swellings in children are common. Most are due to lymphadenopathy secondary to the common acute upper respiratory infections, notably pharyngitis and tonsillitis, that are a feature of normal childhood. They are rarely indicative of serious pathology. Lymphadenopathy is usually self-limiting but may progress to cellulitis, suppuration and abscess formation.

Chronic infections are less common but need to be considered if the swelling persists. Congenital lesions do not always declare themselves at birth; they may present in older children. The onset of the swelling may be precipitated by an acute inflammatory episode.

Neck swellings may involve the parotid and sub-mandibular regions and extend on to the face.

In a very small number of children, a neck swelling will be due to a malignancy. These are most often lymphoproliferative or connective tissue tumours. Squamous carcinoma is extremely rare in children. A child with a neck mass requires an entirely different approach to that required in an adult.¹ Open biopsy is rarely

needed. Nevertheless, it is important to maintain an index of suspicion for malignancy in all persistent neck swellings in children.

ASSESSMENT OF NECK SWELLINGS

There is a broad spectrum of aetiologies for inflammatory lymphadenopathy in children (Table 94.1). Noninflammatory disorders will need to be considered in the differential of a neck mass, especially if there are unusual features. A methodical approach is required with a focus on clinical assessment.

CLINICAL ASSESSMENT

History

- **Age of child:** Most acute lymphadenitis presents in children older than six months. Swellings occurring at or shortly after birth are more likely to be congenital or neoplastic.

Table 94.1 Inflammatory neck nodes in children.

Viral	Infective aetiologies			
	Bacterial	Fungal	Parasitic	Non-infective adenopathy
Upper respiratory: rhinovirus, adenovirus, enterovirus	Acute lymphadenitis: Streptococcus, Staphylococcus, less commonly Gram-negative organisms	Histoplasmosis	Toxoplasmosis	Kawasaki syndrome
Common childhood illnesses: measles, mumps, rubella, varicella	Suppurative lymphadenitis with deep or superficial neck abscess; usually pyogenic organisms (Streptococcus and Staphylococcus)	Uncommon fungal infections (immunocompromised host)	Filariasis	Sarcoidosis
Infectious mononucleosis	Mycobacteria: tuberculosis or 'atypical' mycobacteria	Candida and Aspergillus		Sinus histiocytosis with massive lymphadenopathy
Cytomegalovirus	Other granulomatous bacterial infections: cat scratch disease, actinomycosis, brucellosis, tularaemia, bubonic plague, syphilis			Kikuchi-Fujimoto disease
HIV				PFAPA syndrome (periodic fever, aphthous stomatitis, pharyngitis, cervical adenitis)

- **Duration of swelling:** A short history (a few days) suggests acute inflammation. After six weeks a swelling is regarded as chronic and further investigation should be considered – even earlier if there are suspicious clinical features.
- **Size:** Very large swellings or swellings that progressively enlarge despite antimicrobial treatment should be investigated.
- **Associated symptoms:** A preceding upper respiratory infection is often a feature of inflammatory lymphadenitis. Fever, rhinorrhoea, sore throat and malaise are common. With chronic swellings, enquire about weight loss, night sweats and swellings elsewhere in the body.
- **Contacts:** Enquire about tuberculosis, other infections and exposure to cats, farm animals and ticks.
- **Medical history:** Identify any known illnesses.
- **Family and social history:** Identify any familial disease or congenital anomalies and any relevant social factors. If a diagnosis of human immunodeficiency virus (HIV) infection is suspected then involve a paediatrician.

EXAMINATION OF THE NECK

Site of the swelling

The site of the swelling within the neck provides important information about the possible aetiology.

LATERAL NECK SWELLINGS

Lymph nodes are distributed throughout the neck but the most common site is along the superficial and deep cervical chains. These lie deep to sternomastoid in the upper neck and along its anterior border in the lower neck. Enlarged lymph nodes are the most common cause of lateral neck swellings. The principal differential includes congenital anomalies such as branchial cysts, which may also become acutely inflamed. Vasoformative lesions (see also Chapter 99, Branchial arch fistulae, thyroglossal duct anomalies and lymphangioma), haemangiomas and vascular malformations, including lymphatic abnormalities and benign and malignant neoplasms arising from the neural or connective tissue elements present, as well as rare secondary metastases.

CENTRAL NECK SWELLINGS

The principle causes of a neck swelling in the central area of the neck around the midline are thyroglossal duct cyst, lymph nodes and dermoid cyst. Thyroglossal duct or dermoid cysts may become acutely inflamed. Children can also develop inflammatory and neoplastic thyroid disease (see also Chapter 99, Branchial arch fistulae, thyroglossal duct anomalies and lymphangioma). Lymphatic vascular malformations can occasionally involve this region.

PAROTID SWELLINGS

Acute parotitis (mumps) is common and is due to a self-limiting viral infection. Vaccination for measles, mumps and rubella is now reducing the frequency of mumps and to some degree the clinical awareness of this condition (see also Chapter 97, Salivary gland disorders in childhood).

BACTERIAL PAROTITIS

This occurs in children and may be recurrent. It is usually characterized by acute painful presentation followed by resolution on antibiotics. Occasionally, chronic inflammatory swelling persists and must be distinguished from neoplasia. Vascular malformations and haemangiomas cause swellings in the parotid region. Occasionally, rhabdomyosarcoma or other connective tissue tumours present. Magnetic resonance scanning can be very helpful with this differential diagnosis (see also Chapter 97, Salivary gland disorders in childhood).

SUBMANDIBULAR SWELLINGS

Enlarged lymph nodes, floor of mouth infections, acute sialadenitis and occasionally lymphatic or vascular malformations and congenital 'plunging' ranula all cause swelling in this region (see also Chapter 97, Salivary gland disorders in childhood).

POSTERIOR TRIANGLE SWELLINGS

Most commonly these are lymph nodes but branchial anomalies, vascular malformations and neoplasia enter into the differential diagnosis.

Nature of the swelling

Classical signs of acute inflammation may be present, e.g. redness, tenderness and heat. Chronic swellings usually do not show these signs. If abscess formation has occurred, the clinical sign of fluctuance may be present and the mass may feel cystic. A classical tuberculous abscess lacks the clinical features of acute inflammation ('cold abscess').

HEAD AND NECK EXAMINATION

A careful examination for a source of primary infection should be made. This should include examination of the pharynx, nose and ears as well as looking for any cutaneous lesion.

General examination

Fever, tachycardia or rash should be noted. A general examination should include a search for any associated lymphadenopathy and hepatosplenomegaly. The otolaryngologist may wish to enlist the help of a paediatrician.

Investigation

In many cases no investigation is required. Symptomatic treatment of presumed viral infection or antibiotic treatment of bacterial infection with careful clinical follow-up will result in resolution.

Laboratory and skin tests

If the child is systemically unwell, a full blood count may demonstrate neutrophilia consistent with bacterial infection. A blood count may also be a screening investigation for suspected haematological malignancy. Consider a Monospot test for infectious mononucleosis (see also Chapter 95, Diseases of the tonsil). Serological tests for toxoplasmosis, bartonella (cat scratch disease), or cytomegalovirus (CMV) should be considered for persistent lymphadenopathy. Mantoux or Heaf tests for tuberculosis may be helpful, particularly in the nonimmunized.

Imaging

There is only a limited place for plain radiographs. Films of the chest may be helpful in tuberculosis and a lateral neck view may demonstrate a retropharyngeal mass. Ultrasound examination of a neck mass may be undertaken without sedation or anaesthesia. Ultrasound will help determine if a lesion is cystic or solid. An experienced ultrasonographer can comment on the internal architecture of lymph nodes and may raise suspicion of malignancy. If an abscess is identified, sonography will help with the anatomical relationships of the abscess and with surgical planning.

Computed tomography (CT) scanning may require general anaesthesia in small children. Good anatomical detail is provided and it is helpful in surgical planning. Neither ultrasound nor CT² are absolutely accurate in the diagnosis of abscess and in the presence of strong clinical features surgical exploration should be considered. [**/*]

Magnetic resonance (MR) scanning rarely adds useful information in the case of acute inflammatory lesions but is very useful for vascular malformations, salivary gland and soft tissue masses (see also Chapter 102, Imaging in paediatric ENT).

SPECIFIC CONDITIONS

Viral infections

VIRAL UPPER RESPIRATORY INFECTIONS

Adenovirus, rhinovirus or enterovirus (Coxsackie A and B) may cause reactive lymphadenopathy. This is generally self-limiting.

INFECTIOUS MONONUCLEOSIS

This is an acute infection caused by Epstein–Barr virus (EBV). It occurs mainly in adolescence and is spread by close contact. Fever, fatigue, malaise and an exudative tonsillitis are characteristic. Cervical lymphadenopathy may be massive. Other lymphoid tissue including liver and spleen may be enlarged. There is a characteristic picture on the blood film with the presence of atypical lymphocytes. Serological tests such as Monospot or Paul Bunnell will usually confirm the diagnosis. Although the aetiology is viral, intravenous antibiotics may be needed to treat any coexistent bacterial infection. Ampicillin is contraindicated.

In cases where the acute tonsillitis is associated with airway obstruction, steroids may be considered. On occasion, endotracheal intubation may be required to protect the airway until the swelling subsides.³ Cases with hepatosplenomegaly should be managed in cooperation with a paediatrician (see also Chapter 95, Diseases of the tonsil).

HIV

Infection is associated with repeated opportunistic infections. Most cases of paediatric HIV infection are acquired from the mother by vertical transmission. Acute infection may mimic infectious mononucleosis. Persistent generalized lymphadenopathy including the cervical nodes becomes a feature as the disease progresses. Weight loss and recurrent fevers occur. Following HIV infection it may be years or decades before full acquired immune deficiency syndrome (AIDS) develops. There is significant evidence of increased life expectancy with early retroviral treatment.⁴

Investigation and management should be in cooperation with a specialist in paediatric infectious diseases.

Bacterial infections

ACUTE LYMPHADENOPATHY WITH SUPPURATION

Cervical abscesses

Bacterial infection within a cervical lymph node may progress to cause local cellulitis and abscess (Figure 94.1). Occasionally, a solid mass of inflammatory tissue forms due to coalescence of a group of lymph nodes and this is clinically referred to as a phlegmon. The distinction between phlegmon and abscess is important, as abscesses usually require surgical drainage whereas phlegmon settle with intravenous antibiotics. The most important assessment is clinical. Abscesses are tender, usually reddened and exhibit the clinical sign of fluctuance confirming their cystic nature. Imaging is helpful but not always required.

© Hodder Arnold / Scott-Brown 7E

Figure 94.1 (a) Child with acute cervical abscess; (b) CT scan of the same child.

Many neck abscesses require surgical drainage. This may be performed by a neck incision, which is ideal for superficial lesions and the majority of deep cervical abscesses. A wide-bore needle aspiration may be adequate if the pus has coalesced and liquefied.

Dental abscess

An infected molar or premolar may cause extensive swelling extending into the face and neck and should be considered in the differential of a neck abscess (Figure 94.2).

Retropharyngeal abscess

This occurs typically in the young child (under two years) and is due to suppuration in the loose aggregate of lymph nodes between the pharynx and the prevertebral fascia (Figure 94.3). It is now uncommon but should be recognized because of its potential to cause fatal airway obstruction.⁵ The child is febrile, drooling and may adopt a characteristic posture with the neck flexed and the head extended. Retropharyngeal abscess is a surgical emergency. The child must be admitted for intravenous antibiotics, rehydration and careful observation. Early drainage under general anaesthesia with the help of a

● Hodder Arnold / Scott Brown 7E

Figure 94.2 Dental abscess.

skilled paediatric anaesthetist is indicated if there is any concern about impending airway deterioration. CT scanning will demonstrate the abscess but may itself require anaesthesia and is contraindicated if there is significant airway compromise. Drainage is via the intra-oral route.

Lemierre's syndrome

This is a post-tonsillitis septic thrombosis of the internal jugular vein. It is most often caused by the bacteria *Fusobacterium necrophorum*. It was common in the pre-antibiotic era. Following an episode of tonsillitis, the patient develops high spiking fevers with tenderness and fullness of one side of the neck. (See also Chapter 95, Diseases of the tonsil.) Pulmonary emboli may occur and, untreated, the mortality is high. Incidence in the UK is rising, perhaps related to changing patterns of antibiotic use.⁶ Contrast enhanced CT scanning is usually diagnostic and treatment with intravenous antibiotics and drainage of any abscess is usually curative. The role of anticoagulants is controversial and surgical treatment of the suppurating internal jugular vein is rarely required, although has been used in cases of repeated septic emboli.

MICROBIOLOGY

Group A beta haemolytic streptococcus and *Staphylococcus aureus* are the most common causative organisms for suppuration in the neck. Other bacteria that may be implicated include anaerobes (19 percent); *Haemophilus influenzae*, *Moraxella catarrhalis*⁷ and Beta lactamase positive organisms.

Figure 94.3 Retropharyngeal abscess: (a) plain film showing large prevertebral shadow with compression of the airway; (b) CT scan of same child showing swelling filling the retropharyngeal space.

Mycobacterial infections

Two groups of mycobacterial infections involve the neck in children. The distinction is important and can be challenging. First there are infections caused by *Mycobacterium tuberculosis* (TB). Secondly are a group of infections caused by other mycobacteria. Commonly

referred to as atypical mycobacteria, these are most accurately termed nontuberculous mycobacteria (NTM) (see also Chapter 97, Salivary gland disorders in childhood). They include *Mycobacterium avium intracellulare*, *Mycobacterium scrofulaceum*, *Mycobacterium fortuitum* and *Mycobacterium haemophilum*.⁸

The typical presentation is of a painless firm enlarging mass in the neck. In NTM infection the overlying skin is frequently discoloured (**Figure 94.4**). In children with tuberculosis, weight loss, fever and anorexia may be present.

The differential diagnosis includes lymphoma. To exclude this a tissue diagnosis is usually required. Biopsy specimens are sent for both histopathological examination and for microbiology, including staining and culture specific to mycobacterium. The typical histopathological appearances of tuberculosis are of caseating granuloma formation. Acid and alcohol fast staining bacilli may be seen. However, it may not be possible histopathologically to distinguish tuberculous from NTM infection. Culture of the mycobacterium may take several weeks. In this situation all patients should have a chest x-ray to identify features of tuberculosis. A tuberculous skin test is often helpful. A positive test in a nonimmunized population (such as the United States or children under 13 in most regions of the United Kingdom) is highly suggestive of tuberculous infection. Unfortunately there is an incidence of positive testing with nontuberculous infection and this test is not absolutely diagnostic for tuberculosis. In cases of doubt, antituberculous medication may be commenced pending the outcome of cultures. Genetic probing of the cultured organisms can also be used to try and make the distinction between tuberculous and NTM infection.

The management of NTM lymphadenopathy is controversial. Complete surgical excision of the involved nodes brings about quick disease control and often no further treatment is necessary. [**/*] Prolonged medical therapy is an alternative.⁹ With medical therapy, it is not unusual for the mass to persist for up to 18 months. Treatment is discussed in Chapter 97, Salivary gland disorders in childhood.

SINUS FORMATION AND DISCHARGE

If the nodes have been breached by the infection and there has been spread into the surrounding tissue, then there is a risk of skin breakdown and formation of a sinus. These sinuses often persist for months with troublesome discharge. Once a sinus has formed, there is a strong indication to perform surgery as the constant discharge is extremely disruptive to the life of an otherwise well child. Curettage has been advocated as a treatment for infection that has spread beyond the lymph nodes and is not amenable to complete excision. This may reduce the duration of the disease.

Figure 94.4 (a) MR scan showing large left neck mass; histology confirmed NTM; (b) Skin changes in NTM.

Primary medical treatment of nontuberculous neck masses has been advocated using either macrolide antibiotics based on some *in vitro* experiments¹⁰ or antituberculous

therapy. This usually involves prolonged treatment as the organisms are notoriously resistant to antituberculous therapy. Hawkins and Clark¹¹ showed resolution of neck mass in four of 18 cases by chemotherapy alone.

CAT SCRATCH DISEASE

This is a granulomatous condition characterized by lymphadenopathy with fever and malaise. The disease has been recognized for over 50 years but only recently has the causative organism been identified as the bacteria *Bartonella henselae*. It is spread by close contact with cats.

Patients are mainly under 20 years of age and more than 90 percent have a history of feline contact.^{12,13} Serologic testing has a high sensitivity and specificity. Although there is no medical treatment confirmation of the diagnosis, performing a blood test will reassure parents who often become concerned about possible malignancy.

TULARAEMIA

This is caused by infection with the Gram-negative bacillus *Francisella tularensis*. It rarely infects the neck and is transmitted to humans by rabbits, ticks or contaminated drinking water. Skin or mouth ulcers may be present with associated lymphadenopathy, fevers, malaise and headache. Diagnosis can be difficult but is confirmed by rising serological titres in the convalescent phase of the illness. Treatment is with streptomycin, tetracycline, aminoglycosides or chloramphenicol.

ACTINOMYCOSIS

This is caused by Gram-positive non-spore forming bacteria. The most common human pathogen is *Actinomyces israelii* but there are several other species which can rarely be pathogenic. Approximately 50 percent of cases are cervicofacial. Actinomyces are normal commensals in the oral cavity and infections arise from a breach of the mucosae, e.g. dental extraction. The most common presentation is a slow growing painless mass near the mandible. Local lymph nodes may be involved and in a small number of cases metastasis of disease to liver or brain may occur. Untreated, the mass progresses to fibrosis and chronic suppuration with draining sinuses. A less common presentation is with an acute, warm, tender mass with fever. The presence of sulphur granules on pathological examination is suggestive but not diagnostic. If the diagnosis is suspected, special culture conditions increase the chance of culturing this organism. Most cases are treated by surgical excision followed by prolonged antibacterial therapy, usually penicillin for up to six months.

BRUCELLOSIS

Brucellosis is a zoonosis, i.e. an infection transmitted from animals to humans. It can be acquired through

working with livestock or consumption of unpasteurized dairy products. It is caused by several species of the genus *Brucella* which are small Gram-negative bacilli. There is lymphadenopathy involving the neck and other body regions associated with fever and malaise. Diagnosis is by serology and management is with tetracycline in adults and trimethoprim-sulphamethoxazole in children.

SYPHILIS

This is a spirochaete infection, now rare. Primary syphilis is associated with an ulcer (chancre) and local lymphadenopathy. Early presentation with a neck mass may occur in patients with HIV.

Fungal infections

HISTOPLASMOSIS

Histoplasmosis is caused by the fungus *Histoplasma capsulatum*. It is associated with bird droppings and acquired via airborne spores. Infection in the central USA is very common and typically asymptomatic. In immunocompromised patients, pulmonary and systemic disease may occur. Mucosal head and neck lesions may mimic squamous carcinoma. Biopsy is needed and treatment is surgical excision.

CANDIDA AND ASPERGILLUS

Mucosal candidiasis is a common problem in children but neck masses caused by these infections are extremely rare and limited to immunocompromised patients.

PARASITOSIS

Toxoplasmosis

Infection with the parasite *Toxoplasma gondii* is usually through the ingestion of poorly cooked meat or ingestion of oocytes excreted in cat faeces. Cervical adenitis occurs in more than 90 percent of clinical cases.¹⁴ However, subclinical infection is not uncommon and positive serology may be found in asymptomatic individuals. The lymphadenopathy may persist for months and children may require a biopsy to rule out malignancy. Treatment is rarely required for cervical lymphadenopathy which is self-limiting but the infection responds to sulphonamides and pyrimethamine.

Noninfective inflammatory disorders

SARCOID

Sarcoidosis is a chronic multisystem disorder of unknown aetiology. It mainly occurs in the second decade of

life and is rare in children. It mainly causes generalized and pulmonary symptoms but may involve other parts of the body. Neck masses, parotid masses and facial nerve paresis may result. Cervical nodes are typically bilateral and nontender. The diagnosis is often suspected from the chest radiograph and can be confirmed by biopsy which shows typical noncaseating granulomas (see also Chapter 99, Branchial arch fistulae, thyroglossal duct anomalies and lymphangioma). Treatment is usually conservative although steroids, and in some cases more potent antineoplastic agents, can be used.

Conditions which simulate lymphoma

This heterogeneous group of benign lymphoproliferative disorders is characterized by often prolonged unexplained cervical adenopathy which can give rise to concerns regarding lymphoma. Some authors refer to these conditions as 'pseudolymphomata'. They include Rosai Dorfman disease, Castleman's disease, Kawasaki syndrome and Kikuchi-Fujimoto disease.¹⁵

KAWASAKI SYNDROME

This is an acute multisystem vasculitis of unknown aetiology. It tends to affect children under five years of age and the clinical presentation is similar to many childhood infectious diseases. The diagnosis is clinical and children should have four of the five following criteria:

1. acute nonpurulent lymphadenopathy – usually unilateral;
2. erythema, oedema and desquamation of the hands and feet;
3. polymorphous exanthema;
4. painless bilateral conjunctival infection;
5. erythema and injection of the lips and oral cavity.

There may be a thrombocytosis and pericardial effusion. In the subacute stage, coronary artery aneurysms develop in 15–20 percent of cases. The goal of management is to reduce inflammatory responses with anti-inflammatory or gamma globulin therapy.¹⁶ The vasculitis is self-limiting but unfortunately causes permanent cardiac damage in around 20 percent of untreated patients. All patients should have an initial echocardiogram and cardiac follow-up. A mortality of 1–2 percent is associated with this disease due to the cardiac sequelae.

SINUS HISTIOCYTOSIS (ROSAI DORFMAN DISEASE)

Children present with massive cervical lymphadenopathy which is similar to infectious mononucleosis or

lymphoma. This disease is thought to represent an abnormal histiocytic response to some precipitating cause, possibly a herpes virus or EBV.¹⁷ Fever and skin nodules may be present. Treatment is expectant but biopsy is usually required to rule out malignancy. Histopathologic examination reveals dilated sinuses, many plasma cells and marked proliferation of histiocytes.

KIKUCHI-FUJIMOTO DISEASE

This is an idiopathic disorder, first described in Japan. It is characterized by lymph gland enlargement which may occur anywhere in the body but is typically cervical.

Fever chills and weight loss are common. Women and young adults are more commonly affected. The disease is self-limiting but biopsy is often performed to rule out malignancy. Histology shows a characteristic necrotizing lymphadenitis.

KEY POINTS

- Lymphadenopathy is common in children and rarely requires investigation.
- Viral adenitis is the most common cause of neck swelling.
- Much anxiety can be caused by lesions that simulate lymphoma but careful clinical assessment supplemented by noninvasive investigations, and very rarely biopsy, will provide a diagnosis.
- Immunocompromised patients pose a particular challenge and liaison with a paediatrician is essential in this group of children.

Best clinical practice

- ✓ A blood count is a useful screening investigation for haematological malignancy. [Grade B]
- ✓ Ultrasound will help determine if a lesion is cystic or solid. An experienced ultrasonographer can comment on the internal architecture of lymph nodes and may raise suspicion of malignancy. [Grade B]
- ✓ In NTM, once a sinus has formed there is a relative indication to perform surgery as discharge is extremely disruptive to the life of an otherwise well child. [Grade C]
- ✓ Open biopsy may be the only way to exclude a lymphoma in the noninfective inflammatory lymphoproliferative disorders. [Grade C]

Deficiencies in current knowledge and areas for future research

- The increasing survival of children with malignant disease, often with highly immunosuppressive chemotherapy, will produce therapeutic challenges in the management of infectious disease in the head and neck.
- Pooling of data on relatively uncommon conditions such as NTM may produce better treatment protocols.
- Imaging continues to be refined and as spiral CT scanners permit higher resolution images at lower radiation doses, imaging the architecture of cervical structures will improve.
- Aspiration biopsy cytology has proved disappointing in children and increasing specialization in pathology may expand the role of this technique.

SEARCH STRATEGY

Searches were conducted of the Cochrane Library, Medline, Pubmed and Ovid databases using the key words tonsils, tonsillitis, pharyngitis, sore throat, and carrying out further subsearches for anatomy, microbiology, immunology, complications and therapy. These were complemented by hand searches of current English language texts and the following journals: Journal of Laryngology and Otology, Clinical Otolaryngology, Laryngoscope, Archives of Otolaryngology, Annals of Otolaryngology, International Journal of Pediatric Otolaryngology. The search was complemented by a hand search of the reference list in the MD thesis of Miss Ruth Capper, Doncaster, to whom I pay due acknowledgement.

STRUCTURE AND FUNCTION

Structure

The palatine tonsils consist of paired aggregates of lymphoid tissue. They are located in the pocket formed between the palatoglossus and palatopharyngeus muscles and the overlying folds of mucosa, which make up the anterior and posterior tonsillar pillars. With the lingual tonsils, the adenoids (see Chapter 84, The adenoid and adenoidectomy) and the diffuse aggregates of pharyngeal submucosal lymphoid tissue they make up Waldeyer's ring, a complete circle of lymphoid tissue surrounding the entrance to the gastrointestinal and respiratory tracts. The tonsils share a common structure with lymphoid tissue elsewhere in the gastrointestinal and respiratory tracts including the adenoids and Peyer's patches in the small intestine and within the appendix. Histologically they consist of lymphoid tissue with aggregates of lymphocytes

arranged in a follicular manner and embedded in a stroma of connective tissue. The stratified squamous mucosal covering of the tonsils extends irregular convoluted invaginations into the parenchyma forming pits or crypts. Microorganisms, desquamated epithelium and food debris are frequently present within the crypts and may be implicated in the development of acute and recurring inflammation.

Normal flora

The range of organisms cultured from the tonsils both in health and disease is extremely variable, with recognized differences in bacterial flora retrieved from surface and from core samples.^{1,2} The organism most commonly identified from the surface of the tonsil in disease is the group A beta haemolytic streptococcus (GABHS). Up to 40 percent of asymptomatic individuals will also have a

culture positive for this organism.^{3,4} Other surface organisms include *Haemophilus*, *Staphylococcus aureus*, alpha haemolytic streptococci, *Branhamella* sp., *Mycoplasma*, *Chlamydia*, various anaerobes and a variety of respiratory viruses.^{5,6} [****] In a study of core samples obtained by fine needle aspiration in health and disease, core samples of normal tonsils usually failed to grow pathogenic organisms.⁷ In recurrent tonsillitis the samples grew a range of pathogens but the predominant organisms were *Haemophilus influenzae* and *S. aureus*. A mixed flora was also common. Beta haemolytic streptococci were less common. [****]

Function: role of the tonsils within the immune system

The tonsils have no afferent lymphatics. The lymphoid germinal centres are located immediately submucosally. They contain both B and T lymphocytes. B cells predominate, implying that both cell-mediated and humoral immune function is present in the tonsil and that B lymphocytes are actively produced in the tonsil. These cells have the capability to synthesize specific antibodies. They appear to be responsible for the final differentiation, induced by exposure to antigen, of B cells to principally immunoglobulin (Ig)G and IgA plasma cells. They allow positive selection of B cells according to receptor affinity for antigen and provide B cells specific for mucosal effector sites. It seems likely that they generate B cells which express polymeric IgA and which migrate to the upper respiratory tract mucosa and associated 'front line' mucosal surfaces. Contact with allergens in the upper respiratory tract therefore enhances local immunity and also contributes to the development of systemic immunity. Inflammatory change within the tonsils may be a manifestation of this function – hence the old adage that the function of the tonsils is 'to develop tonsillitis'. Whether or not tonsillitis represents a swamping of defence mechanisms at local level or an exaggeration of the normal response is not known. The fact that tonsillitis is often recurrent suggests that there may be some intrinsic defect either in the tonsils themselves or in the patient's immunity. The observation that tonsillitis tends to become less frequent with time suggests speculatively that the problem lies within the immune system rather than within the end organ itself. However, it has been shown that polymeric IgA production in tonsillar B cells is markedly reduced in children with recurrent tonsillitis. This suggests that conservation of tonsillar tissue is desirable, a point frequently emphasized by authors outwith the UK. There is no evidence that tonsillectomy *per se* results in impaired immunity, indeed, the converse appears more likely. In spite of a sizeable literature discussing the relationship of immune function to disease of the tonsils there is no tenable evidence of significant immune compromise, presumably as a result

of the extensive 'backup' in the immune system.⁸ The precise role of bacteria and viruses in this process is also controversial. The evidence available suggests that they may act synergistically, with the presence of latent viruses (particularly Epstein–Barr virus, adenoviruses and herpes simplex) sensitizing the pathogenic bacteria frequently present on the tonsils of asymptomatic individuals.⁹ [**]

INFLAMMATORY DISORDERS OF THE TONSIL

Acute tonsillitis

PRESENTATION AND FLORA

Acute inflammatory episodes affecting the tonsils may occur as an isolated episode, or in association with a viral upper respiratory illness including generalized pharyngitis (see Figures 95.1 and 95.2). Tonsillitis may also present as part of a systemic infection such as infectious mononucleosis (see under Infectious mononucleosis below) when severe tonsil inflammation may be a prominent part of the clinical presentation. Classically, the causative organism in acute suppurative tonsillitis is

© Hodder Arnold / Scott-Brown 7E

Figure 95.1 Tonsillopharyngitis (appearances could be either viral or bacterial).

© Hodder Arnold / Scott-Brown 7E

Figure 95.2 Severe tonsillitis (GABHS were isolated in this case but the appearances are nonspecific).

GABHS. A wide variety of other organisms including anaerobes and viruses may be implicated in a clinically indistinguishable illness although whether they are primarily causative is undetermined.^{3,4} [**] Epidemiological data about the true incidence of tonsillitis as opposed to pharyngitis or sore throat is confounded by the fact that there is no robust definition of tonsillitis, making assessment of the outcomes of management difficult. Studies of sore throat management frequently use bacteriological criteria for diagnosis but this does not reflect the situation in clinical practice nor is it a reliable 'gold standard'.

EPIDEMIOLOGY

Sore throat is a common reason for presentation to a primary care physician. The frequency in the UK is 0.1 consultations per capita per annum.¹⁰ [**] Not all these sore throats will be due to true tonsillitis; however, there are no case control or population studies of the epidemiology of sore throat in the recent literature, let alone any specifically looking at tonsillitis.¹¹ Sore throat affects both sexes and all age groups but is much more common in children and during the autumn and winter months.^{12,13} [**]

CLINICAL EVALUATION

The diagnosis of acute tonsillitis is clinical. It is based on a history of a pyrexial illness, sore throat with a painful swallow, and the finding of pharyngeal erythema with or without tonsillar exudates and painful cervical adenopathy.

Evaluating aggregated symptom complexes including tonsillar exudate, anterior cervical lymphadenopathy, the absence or presence of cough, pharyngeal erythema and the level of pyrexia has been attempted but the results of these studies are conflicting and the conclusions unconvincing. There is good evidence that the sensitivity and specificity of clinical diagnosis alone is between 20 and 50 percent.¹⁴ [***] It should not be relied upon in diagnosis of bacterial or viral aetiology.

AETIOLOGY OF INFLAMMATORY DISEASE

The precise aetiology of inflammatory disease of the tonsils remains shrouded in controversy. It is widely accepted that both bacteria and viruses play a part in acute inflammation either separately or together. It is also probable that factors within the immune system of the individual patient render them susceptible to episodes of infection, which may be isolated or recurrent, but these remain unquantified and studies of immunoglobulin levels in such patients have been inconclusive. The point at which the tonsils become the cause of the disease rather than simply the site is undetermined, if indeed this ever becomes the case.

With the exception of tonsillitis associated with infectious mononucleosis, there is no evidence that viral tonsillitis is more or less severe than bacterial tonsillitis or that the duration of the illness varies significantly in either case.

DIAGNOSIS OF CAUSATIVE AGENT

Although the precise diagnosis may be of interest academically, from the practical point of view it is probably of little relevance in management. Both bacterial and viral tonsillitis tend to resolve quickly without treatment in most cases.^{15,16} [****] Precise diagnosis of the causation may be of more relevance in protracted illness but is difficult and imprecise in practice. Possible options for diagnosis in clinical practice include clinical assessment, bacteriological culture or rapid antigen testing (RAT) of a throat swab for GABHS. RAT is in common use in North America but is seldom used in the UK.

MICROBIOLOGICAL INVESTIGATION

Bacteriological culture of a throat swab may yield a positive culture for GABHS but this does not conclusively prove that the organism is causative. The incidence of a positive culture may be as high as 40 percent in asymptomatic carriers.^{3,4} The organism has also been isolated from tonsillitis cases with no serological evidence of infection. In addition, the organisms cultured from the surface of the tonsil may vary greatly from the bacterial flora deep within the tonsillar crypts. It is by no means certain which is likely to be the more relevant to clinical symptoms.^{1,2,3,4,17} [***] Inevitably, there is a delay of 24–48 hours before results are available, rendering its value limited in treating a short-lived self-limiting illness.

RAPID ANTIGEN TESTING

The use of RAT as an office procedure has superficial attractions, principally speed in reporting results (ten minutes), but the sensitivity measured against throat swab culture (itself a doubtful gold standard) was variable across trials at between 61 and 95 percent with specificity from 88 to 100 percent.¹⁸ There may be variation between different laboratories.¹⁹ [**] The costs of both throat swab culture and RAT are not insignificant.

PRIMARY MANAGEMENT

The management of acute tonsillitis is principally supportive, with the use of analgesics and adequate hydration until the symptoms subside. The choice of analgesia is governed by the severity of symptoms but the majority will find paracetamol in full dosage adequate. Nonsteroidal antiinflammatory drugs may be used in more severe cases but the higher side-effect profile makes them a second-line treatment.

SPECIFIC TREATMENT

The relatively complex interplay between bacteria and viruses in acute tonsillitis is not fully understood and if no bacteria are cultured a viral aetiology is assumed. Even if bacterial pathogens are identified, their significance is uncertain. The average duration of an episode of acute tonsillitis seen in general practice is two to three days, with evidence that although the prescription of antibiotics will shorten the illness and may reduce the risk of sequelae this is not clinically significant.^{15, 20, 21}

A Cochrane review of antibiotics for sore throat concluded that there was evidence of benefit in shortening the illness by a mean of one day around day three of the illness, by which time approximately 50 percent of patients will have settled spontaneously (OR 0.16; 95 percent CI 0.09, 0.26 with a positive throat swab; OR 0.65; 95 percent CI 0.38, 1.12 with a negative swab). They also found a reduction in the frequency of suppurative complications including quinsy (OR 0.16; 95 percent CI 0.07–0.35), but concluded that ‘blanket’ or routine prescription of antimicrobials was not justified.²⁰ There is evidence that patients prescribed antibiotics for sore throat are more likely to reattend for antibiotic prescription on subsequent occasions,²² and the risks of widespread indiscriminate antibiotic prescription include genesis of resistant organisms, allergy and anaphylaxis. There are numerous studies of the efficacy of various alternative antibiotics (predominately cephalosporins) over penicillin in general and specifically in cases of proven GABHS infection. These show only marginal evidence of increased benefit insufficient to justify their use.

In those patients in whom the illness shows no sign of improvement within 48–72 hours or in whom there is clinical concern because of the severity of symptoms, antibiotic therapy is appropriate and the drug of choice remains benzylpenicillin. The literature is unclear about the optimal duration of therapy but the recommendations in the British National Formulary, supported by recent evidence,²³ are for a seven-day course.

In cases where there is clinical concern about the severity of the illness, antibiotics should not be withheld.

Recent evidence from several randomized controlled trials²⁴ suggests that a single dose of dexamethasone as adjuvant therapy was of significant benefit in reducing pain in acute pharyngotonsillitis with no evidence of predisposition to abscess formation with the use of steroids. [****]

Complications of acute tonsillitis

Acute tonsillitis may be complicated by systemic sepsis, including septicaemia and septic arthritis. GABHS may cause an acute exanthematous reaction with a macular rash – scarlet fever. The noninfective sequelae

of GABHS – rheumatic fever and glomerulonephritis – are considered below under Immune complex disorders.

PERITONSILLAR ABSCESS

The principal complication of tonsillitis is peritonsillar abscess (quinsy) in which a collection of pus forms in the potential space between the tonsil and its bed. Prior to the formation of pus there is frequently a period of peritonsillar cellulitis without abscess formation. Clinically, the patient presents with a severe pharyngitis lateralized to one or other side, often with marked associated lymphadenopathy. There may be severe trismus limiting access for examination and treatment. This results in a severe local and systemic illness which may, if untreated, result in the spontaneous discharge of pus when the abscess points. More commonly, the course of the disease is modified by antibiotic therapy, needle aspiration or incision and drainage in hospital. The organism most commonly cultured from this pus is beta haemolytic streptococcus. Infection with other organisms such as *Streptococcus viridans*, *S. aureus*, *H. influenzae* and various anaerobes may also occur with anaerobes being commonly isolated if appropriate techniques are used.^{25, 26} [****] In severe cases airway compromise and dehydration due to the inability to swallow result, which may necessitate hospital admission for intravenous fluid therapy. This may occasionally happen in severe tonsillitis without abscess formation.

In such cases immediate hospital admission and experienced clinical assessment of the airway is essential. Unskilled attempts to examine the throat may precipitate complete airway obstruction and must be avoided (Figure 95.3). Peritonsillar abscess formerly was regarded as an absolute indication for ‘interval tonsillectomy’ but most clinicians now prefer to take other factors

© Hodder Arnold / Scott-Brown 7E

Figure 95.3 Peritonsillar abscess (swelling is predominantly unilateral).

into account, for example a history of frequent tonsillitis. The majority of otolaryngologists are agreed that a second quinsy is a reasonable indication for operation. Tonsillectomy during the acute phase of the abscess has been established as a safe procedure but opinions differ about whether or not this is the most appropriate management for the condition. Protagonists emphasize the virtues of the avoidance of a second admission, convalescence from only a single episode, avoidance of loss to follow-up for interval tonsillectomy and the rapid relief of symptoms. The procedure requires emergency scheduling and the services of an anaesthetist experienced in the management of the difficult airway.

The release of a large amount of pus into the posterior aspect of the oral cavity, either spontaneously or therapeutically, carries with it the risk of aspiration, especially in severely ill patients. The use of local anaesthesia prior to incision exacerbates this risk, which can be avoided, and satisfactory resolution hastened by aspiration of the abscess using a wide bore needle and syringe together with antibiotic therapy. This is now the management of choice. The antibiotics usually employed are high-dose penicillin intravenously or a cephalosporin but will be guided by bacteriology of the aspirated pus. Some clinicians also use metronidazole and this is logical as a significant proportion of peritonsillar abscesses grow anaerobes.^{26, 27}

RETROPHARYNGEAL ABSCESS

A rare but serious complication of acute tonsillitis is retropharyngeal abscess, presenting mainly in infants and young children aged less than five years. It presents when infection has tracked into the lymphoid tissue between the posterior pharyngeal wall and the prevertebral fascia. The child is systemically ill and there may be evidence of airway compromise or an associated neck abscess. A plain x-ray of the neck may be helpful and the diagnosis can be confirmed by ultrasound or computed tomography (CT) scanning provided the child is well enough for investigation. In one study the sensitivity and specificity of CT in detecting pus was 81 and 57 percent, respectively. CT findings should, therefore, be interpreted with caution and correlated with the clinical picture in planning management. Treatment is initially high-dose antibiotic therapy with urgent incision and drainage when pus formation is suspected, under general anaesthesia with the airway protected by intubation by a skilled and experienced anaesthetist.²⁸ [**] The abscess is usually drained perorally but occasionally external drainage via the neck may be appropriate. Rarely, tracheotomy is necessary. Retropharyngeal abscess due to tuberculosis, at one time relatively common, still occasionally occurs, more commonly in the developing world, and requires specific antibiotic therapy (see Chapter 94, Cervicofacial infections in children).

PARAPHARYNGEAL ABSCESS

Peritonsillar and retropharyngeal abscess may occasionally be complicated by spread of infection to the parapharyngeal space with formation of a large abscess, which may require external drainage. The patient is usually severely systemically unwell, with severe trismus and possibly airway compromise. Management is urgent and if this diagnosis is suspected, imaging by ultrasound and CT scanning may be helpful in both diagnosis and in planning intervention, as noted above. The use of broad-spectrum antibiotics intravenously is essential and initial therapy should include cover against streptococci and anaerobic organisms. Deep neck space sepsis may be complicated by progressive, life-threatening spread of infection including mediastinitis and even retroperitoneal sepsis. Marked neck swelling, airway compromise and female gender appear to be predictive of higher risk cases. Vigilance and a proactive management policy are thus essential in all cases (Figure 95.4).²⁹ [**]

LEMIERRE'S SYNDROME

This is a rare and potentially fatal complication of oropharyngeal infection characterized by septic thrombophlebitis in the internal jugular vein, sometimes in association with metastatic abscesses. The organism is typically a fusiform bacillus. The condition should be considered when there is severe neck pain, septicaemia or a prolonged fulminant course in a patient with infection in the upper aerodigestive tract.³⁰ It has also been described secondary to tympanomastoid infection. Skilled imaging will help to show the presence of a thrombus in

Figure 95.4 CT scan of parapharyngeal abscess (gas is visible in the extensive abscess cavity extending from the deep parapharyngeal space to lateral to mandible superficially).

the neck veins (**Figure 95.5**). Treatment is with prolonged (six weeks) antibiotics, for example a beta-lactam with metronidazole or amoxycillin-clavulanate. Anticoagulation may be considered if there is evidence of spreading thrombophlebitis. There is a significant mortality.^{31, 32}

IMMUNE COMPLEX DISORDERS

Acute tonsillitis and pharyngitis caused by GABHS are occasionally complicated by disease related to immune complex formation generated as part of the immune response to the infection.

The two important diseases resulting from this phenomenon are acute rheumatic fever and acute glomerulonephritis. The incidence of these disorders is declining in the developed world but they are still common in certain ethnic groups, in particular, Australian Aborigines and New Zealand Maoris. The reasons for this are not clear but may be related to social as well as genetic factors. In the UK there is no evidence that treating acute tonsillitis aggressively with antibiotics has resulted in prevention or reduction in incidence of these complications. In communities where rheumatic fever is common, antibiotic therapy for sore throat may have a role in reducing the incidence of this complication.²⁰ [**]

TONSILLITIS AND PSORIASIS

There is a probable association between acute tonsillitis due to GABHS and exacerbations of psoriasis, particularly of the guttate variety where numerous small psoriatic

lesions appear to be generated by each episode of acute tonsillitis. This appears to be an immune phenomenon. Some dermatologists and otolaryngologists advocate tonsillectomy but there is no good evidence that this relieves the condition.³³ The most current (2003) review of the efficacy of antibiotic therapy and of tonsillectomy in children with psoriasis identified only one controlled trial, which found no significant effect for antibiotics in psoriasis. No controlled trials evaluating the effect of tonsillectomy were identified. Uncontrolled data suggest benefit in one-third to half of patients with tonsillectomy but 7 percent reported worsening of their condition after surgery.³⁴ [**]

RECURRENT TONSILLITIS

In a significant but unknown proportion of patients, acute episodes appear to follow a pattern of recurring infection every few weeks or months. This sequence of episodes may gradually abate but in some individuals runs a course amounting to several years. There is currently no way of predicting those individuals in whom the condition may run a protracted course, and epidemiological data are lacking to allow accurate generalizable prognostication about how long the susceptibility to recurrent infection will last. Supportive measures continue to be appropriate and management of more severe symptoms may, again, warrant antibiotic therapy. Some clinicians have used low-dose penicillin if episodes are happening close together but there is no convincing evidence of benefit from this or that any specific antibiotic is effective in aborting recurrent attacks of tonsillitis. The medical treatment of recurrent tonsillitis remains an elusive goal.

SUBACUTE TONSILLITIS

Some patients follow what might be termed a subacute course where they are never free of low-grade discomfort in the throat associated with enlarged inflamed looking tonsils punctuated with acute episodes which may be either mild or severe.

CHRONIC TONSILLITIS

A further category of patients complain of chronic low-grade symptoms affecting their quality of life because of throat discomfort, and the production of unpleasant smelly white or yellow debris from the tonsillar crypts. Rarely, this debris may become inspissated, calcify and form a tonsillolith, which may itself be complicated by acute sepsis. Sufferers may also complain of a feeling of low-grade ill-health, which they and their medical attendants may attribute to chronic tonsil sepsis. There is no scientific evidence addressing natural resolution and general morbidity, or the relationship to identifiable tonsillar pathology in these patients.

Figure 95.5 Ultrasound scan of neck veins in Lemierre syndrome showing presence of thrombus (arrowed).

In children, historically, a very wide range of ailments including recurrent abdominal pain, general ill-health, failure to thrive and low body weight have been attributed to infection of the tonsils but there is no real scientific evidence of this. Conversely, although removal of the tonsils has been claimed to result in increased growth rate and improvement in general health, scientific evidence for this is not robust.

Infectious mononucleosis

Acute pharyngotonsillitis is a frequent manifestation of infectious mononucleosis. This disease, commonly seen in young adults, is caused by the Epstein–Barr virus (EBV), one of the B lymphotropic human herpes viruses. In addition to its throat manifestations the disease causes severe systemic upset, haematological and liver function disturbance and splenomegaly, making the spleen vulnerable to abdominal trauma for a period of a month after cessation of symptoms. This is important in young people involved in contact sports. Diagnosis is by the Monospot blood test but this must be interpreted with caution, as the test sensitivity is <50 percent in children and 70–90 percent in adults. Confirmation is by specific EBV antibody tests. Among this group of patients symptoms are often serious, with dysphagia and occasionally dehydration from poor oral intake (Figure 95.6).

Although the disease is viral, secondary infection of the tonsils happens in up to 30 percent of cases, commonly with beta haemolytic streptococci; antibiotics are routinely prescribed, usually penicillin in high dosage intravenously in those patients admitted to hospital. Occasionally, metronidazole is added to this regimen although some clinicians favour second- and third-generation cephalosporins as an alternative.

Ampicillin must be avoided in this condition as patients may suffer a severe allergic rash in consequence.

If there is extreme swelling of the tonsils such that compromise of the airway and severe difficulty with

© Hodder Arnold / Scott-Brown 7E

Figure 95.6 The throat in infectious mononucleosis (yellow slough is typical).

swallowing results, a short course of high-dose corticosteroids is frequently employed as an adjunct, with evidence of benefit from several uncontrolled studies.^{35,36} [**] Steroids should not be employed routinely in view of the risks in this disease, which is associated with lymphoproliferative disorders. Steroids should only be employed in combination with antibiotics. There is no evidence at present to support the use of antiviral medication such as acyclovir in this disease.³⁷

Specific infections

These include syphilis and tuberculosis. Owing to their relative rarity in the developed world they may potentially be difficult to diagnose. The lesion in syphilis classically takes the form of a 'punched out' ulcer but this is not invariable and, likewise, the appearances in tuberculosis may vary. The main differential diagnosis is with neoplasm and diagnosis is usually made by biopsy of the lesion.

NONINFLAMMATORY DISEASE

Asymmetry

A recent study of tonsil size after tonsillectomy revealed no significant difference in cases of apparent asymmetry.³⁸ [**] Tonsil asymmetry is not an absolute indication for tonsillectomy but in such cases, particularly in adults, the clinician should be alert for the possibility of neoplasia, notably lymphoma.

In clinical practice the apparent size of the tonsils *per se* is not well correlated with disease within them. The tonsils often swell when acutely inflamed, but there is wide variation in the degree to which the tonsils are buried in the lateral pharyngeal wall giving a false impression of the size of the structures themselves. The tonsils tend to involute during late childhood and early adult life, but in the presence of disease may remain prominent into adulthood. Indeed, some asymptomatic adults have impressively large tonsils. The rate of involution varies between individuals and sometimes this process varies between the two tonsils, giving an asymmetric appearance.

Spontaneous tonsillar haemorrhage

Occasionally, spontaneous bleeding from inflamed tonsils may take place but this is rarely serious. This may also happen in response to minor trauma in uninfamed tonsils. It may respond to cautery under local anaesthesia and, occasionally, if persistently troublesome, tonsillectomy may be indicated.

Neoplasia

Asymmetry of the tonsils may give rise to the suspicion of malignancy as may an irregular or ulcerated appearance of one of the tonsils. In childhood it is not unusual for the tonsils to involute asymmetrically and, accordingly, a disparity in size of the tonsils is not always an indication for biopsy in childhood.³⁸ However, any unusual appearances should be treated with caution and further investigated. This will normally include a full ENT examination with special attention to the neck, CT or magnetic resonance scanning of the neck, chest and abdomen if appropriate, followed by panendoscopy and excision biopsy, particularly in adults.

Lymphoma

In keeping with a structure primarily of lymphoid origin, lymphoma may occur within the tonsils and although this is most likely in the adult age group, lymphoma is not unknown in childhood. The management of this disease includes detailed staging of the disease and treatment modalities may encompass surgery, radiotherapy and/or chemotherapy. The details are covered in Chapter 98, Tumours of the head and neck in childhood.

Squamous carcinoma

In common with the rest of the upper aerodigestive tract and oral cavity, in particular, squamous carcinoma is the most common malignancy encountered. It is generally a disease of adult life and is covered in Chapter 193, Oropharyngeal tumours.

Obstructive sleep apnoea syndrome of childhood

The entity of obstructive sleep apnoea of childhood is an increasingly recognized disorder resulting in impaired functioning due to exhaustion, failure to thrive and possibly leading to cardiovascular strain and the later development of pulmonary hypertension. The tonsils and adenoids are very significantly involved in the genesis of this disorder and adenotonsillectomy frequently indicated in its management. The condition and its management are covered in detail in Chapter 85, Obstructive sleep apnoea in childhood.

KEY POINTS

- Acute tonsillitis is common and self-limiting.
- Complications are rare.
- Treatment is largely symptomatic with an emphasis on analgesia and rehydration.

- Antimicrobial therapy has a small but measurable effect on outcome.
- The tonsil rarely may be the site of presentation of lymphoma or malignant disease.

Best clinical practice

- ✓ In acute tonsillitis clinical diagnosis alone should not be relied upon in distinguishing between a bacterial or viral aetiology. [Grade B]
- ✓ Both throat swab culture and RAT are of questionable value in guiding prescription of antibiotics for sore throat. [Grade B]
- ✓ Widespread indiscriminate antibiotic prescription promotes the genesis of resistant organisms, allergy and anaphylaxis. There is no justification for routine use of antibiotics in children with sore throat. [Grade A]
- ✓ In those patients in whom the illness shows no sign of improvement within 48–72 hours or in whom there is clinical concern because of the severity of symptoms, antibiotic therapy is appropriate and the drug of choice remains benzylpenicillin. A seven-day course is usually adequate. [Grade C]
- ✓ A single dose of dexamethasone as adjuvant therapy reduces pain in acute pharyngotonsillitis. [Grade B]
- ✓ Aspiration using a wide bore needle and syringe, together with antibiotic therapy, is now the management of choice for quinsy. As a significant proportion of peritonsillar abscesses grow anaerobes, metronidazole should be considered. [Grade C]
- ✓ Treatment of both parapharyngeal and retropharyngeal abscess is initially high-dose antibiotic therapy. When pus formation is suspected, incision and drainage under general anaesthesia, with the airway protected by intubation by a skilled and experienced anaesthetist is recommended. [Grade C]
- ✓ Ampicillin must be avoided in infectious mononucleosis as patients may suffer a severe allergic rash in consequence. [Grade C/D]
- ✓ Systemic glucocorticoids are of value in infectious mononucleosis where there is extreme swelling of the pharyngeal mucosa with impending airway compromise. [Grade C/D]

Deficiencies in current knowledge and areas for future research

- The role of the tonsil in the development of immunity needs to be more fully understood.
- Data to shed light on the natural history of recurrent tonsillitis and define any subgroups in which natural

resolution of recurrent symptoms is likely to happen would be helpful.

- The precise place and value of antibiotic therapy is still not fully defined. Robust randomized controlled trials of antibiotic therapy versus placebo in sore throat/tonsillitis, both in the acute single episode situation and in recurrent tonsillitis, are required. The results should be applicable to everyday practice.

SEARCH STRATEGY

The opinions in this chapter are supported by a Medline search using the terms tonsil, tonsillectomy and child. Reference was also made to the Cochrane Library. This was supplemented by a hand search of current journals and by reference to the published results of the National Prospective Tonsillectomy Audit available on the Royal College of Surgeons of England website (www.rcseng.ac.uk). The UK Department of Health (www.dh.gov.uk) and the National Institute for Health and Clinical Excellence (NICE) (www.nice.org.uk) websites were also consulted.

INTRODUCTION

Tonsillectomy is one of the most frequently undertaken procedures in otolaryngology. The indications remain controversial. Children are offered surgery primarily to reduce the frequency and severity of recurrent sore throats. A smaller number will have tonsillectomy – often with adenoidectomy – for relief of airway obstruction. This is discussed in Chapter 85, Obstructive sleep apnoea in childhood. This chapter focuses on the role of tonsil surgery in recurrent sore throats in children.

HISTORY OF TONSILLECTOMY

Celsus in ‘De Medicina’ (14–37 AD) described ‘induration’ of the tonsils, which he advised could be removed by dissection with the fingernail. If this was not possible they could be grasped with a hook and pulled out with a ‘bistoury’.¹ Improved instrumentation – particularly the snares and ‘guillotines’ used by Morrel McKenzie² – led to

popularization of the operation in Victorian England. Sir Felix Semon (1849–1921) removed the tonsils from several of Queen Victoria’s grandchildren and the procedure became fashionable in the drawing rooms of the aristocracy.³ It was said to cure a variety of childhood ailments.⁴ Throughout much of the twentieth century, the practice – particularly in the UK and the USA – of more or less indiscriminate tonsillectomy (Figure 96.1), with a small but measurable mortality, led to hostility among paediatricians and public health physicians.⁵ The criteria for offering tonsillectomy have changed significantly over the years and are now much more stringent.

THE EVIDENCE-BASE

Efficacy

Despite the popularity of tonsillectomy and the enthusiasm with which it is offered and sought, high quality

evidence of efficacy is sparse.⁶ A systematic review concluded that there was little evidence on the use of tonsillectomy for recurrent throat infection⁷ and a Cochrane review concludes that there is no evidence from randomized controlled trials (RCT) to guide clinicians in formulating guidelines for surgery in children or adults.⁸ There is no good evidence that any benefit from tonsillectomy for recurrent sore throat in children is sustained for more than two years after surgery.

The most celebrated trials make up the 'Paradise study' reported in 1984.⁹ These randomized and nonrandomized controlled trials prospectively compared groups of children who met strict entry criteria and who received surgery (tonsillectomy with, in some circumstances, adenoidectomy) or nonsurgical intervention. Participation was dependent on children having a history of seven episodes of sore throat in the year prior to the study, five or more in the preceding two years or three or more in each of the preceding three years. Well-documented clinical features had to be demonstrated to ensure eligibility. These trials showed that in these 'severely affected children' tonsillectomy was efficacious for two years, and possibly for a third year. [****] Efficacy was measured by a reduction in the number and/or severity of throat infections. Many of the children treated nonsurgically improved spontaneously. Such benefits as there were from surgery were slight. Critics point out that the study was poorly randomized. Children randomized to the nonsurgical group proceeded to surgery at the subsequent request of the parents. Children having adenoidectomy, as well as tonsillectomy, were included, making it impossible to exclude this intervention as relevant to the outcome of treatment. Children in the control limb of the study had active therapy, which may have minimized the morbidity.

A number of randomized controlled studies of varying but generally poor quality have subsequently contributed

little. The 'Paradise' group has now reported on less severely affected children. Two parallel randomized controlled trials compared surgery with nonsurgical management for children with a history of recurrent episodes of throat infection, but with less stringent entry criteria than for the original studies. These reduced standards were considered to better reflect accepted practice, but were slightly more rigorous than the widely accepted USA guidelines as suggested by the American Academy of Otolaryngology Head and Neck Surgery, i.e. 'three or more infections of tonsils and/or adenoids per year despite adequate medical therapy'.¹⁰ The incidence of throat infection was significantly lower in the surgical groups than in corresponding control groups during each of the three follow-up years. Adenotonsillectomy was no better than tonsillectomy alone. Benefits were marginal, such that the authors concluded that the benefits were outweighed in this group of children by the morbidity and risks of the operation.¹¹ [****]

A good quality open randomized controlled trial in the Netherlands – where surgical intervention rates for recurrent sore throats are considerably higher than in the UK or the USA – looked at 300 children under the age of eight years. Children who fulfilled the criteria of the original Paradise study (i.e. severely affected children) were excluded, so this study looked only at those with mild symptoms. Adenotonsillectomy was compared with watchful waiting. A number of outcome measures – including health-related quality of life and the frequency of episodes of pyrexia – were considered. The authors concluded that adenotonsillectomy had no major clinical benefits over watchful waiting in children with mild upper respiratory symptoms.^{6,12} [****] It must be stressed that both of these studies looked at less severely affected children. In each case the criteria for intervention were considerably less robust than suggested by the Scottish Intercollegiate Guidance Network (SIGN)

guidelines (www.sign.ac.uk) and in the Netherlands's study adenoidectomy was routinely combined with tonsillectomy.

Perhaps inadequate knowledge of the natural history and expected outcome of recurrent sore throats in children has bedevilled the quest for a sound evidential base for current practice. Preliminary data from a study conducted during the 'tonsillectomy embargo' in the UK in 2001 resulting from concerns about variant Creutzfeldt-Jakob disease (vCJD) transmission (see Tonsils and variant Creutzfeldt-Jakob disease) suggests that spontaneous improvement is to be expected in adults.¹³ [**/*] Given that overall the frequency of recurrent sore throat appears to decrease with time, there is no evidence predicting the rate of such improvement or which looks at any difference in natural history in those presenting in childhood compared with those presenting in adult life.

In a randomized controlled trial in adults, 36 participants underwent immediate tonsillectomy. The control group – 34 patients – remained on a waiting list. Follow-up was short but at 90 days, streptococcal pharyngitis had recurred in 24 percent of the control group and in 3 percent of the tonsillectomy group. The authors concluded that adults with a history of recurrent streptococcal pharyngitis were less likely to have further streptococcal or other throat infections or days with throat pain if they had their tonsils removed.¹⁴ The morbidity associated with the operation must be considered and may outweigh any benefits.¹⁵ This study did not include children.

Studies with a less rigorous design than the RCT provide anecdotal evidence of improvement following surgery. The overwhelming view of clinicians is that in judiciously chosen patients tonsillectomy brings about significant benefit. The results of the Scottish Tonsillectomy Audit found a high level of satisfaction among those undergoing surgery (97 percent satisfaction rate at one year).¹⁶ [**/*] There are, however, severe limitations in using satisfaction rates as an outcome measure and the follow-up was relatively short.

Current practice

Tonsillectomy in children is one of the most frequently performed operations in the developed world. Although numbers are declining from a peak of over 200,000 annual tonsillectomies in the 1950s (UK), some 52,000 tonsillectomies were performed in England under the National Health Service in the year 2003/04. Data from the Department of Health Statistics show that around 30,000 of these were in children with an approximately equal gender ratio (www.dh.gov.uk). The majority are for recurrent sore throats with most of the remainder for airway obstruction. Parents in the UK initially present to a general practitioner. Referral patterns are dictated by thinking in primary care and many parents have firm

views by the time they see an otolaryngologist. Despite the availability of guidelines and protocols in practice, a decision to undertake tonsillectomy is made by negotiation between the parent/carer and the otolaryngologist. Some units have introduced nurse-led clinics where strict protocols are used to determine eligibility for surgery. It will be illuminating to see if these protocols have a material effect on surgery rates.

Sociocultural factors

There is no published evidence that the pattern of disease varies by racial, ethnic, climatic or cultural factors across the globe, but there are wide variations in the rate of tonsillectomy by geographical region.¹⁶ [***] A quoted incidence of 6.5 per 10,000 children in the UK National Health Service contrasts with 11.5 per 10,000 in the Netherlands and 5 per 10,000 in the USA. The figures for the UK may be higher as an estimated one-sixth of otolaryngology interventions occur in private practice where figures are not as widely available. In the 2005 National Prospective Tonsillectomy Audit (NPTA) (www.rcseng.ac.uk), some 13 percent of procedures were performed in independent hospitals. In the Scottish Tonsillectomy Audit, sizeable variations in tonsillectomy rate were found between different regions in the same country, from four per 10,000 in Forth Valley to ten per 10,000 in Dumfries and Galloway. In the developing world, the incidence of surgery is much lower, related perhaps to access to health care and parental expectations and preferences.

Tonsillectomy is more common in large conurbations suffering higher levels of deprivation.¹⁷ [**] Recent work suggests that social class and parental smoking does not influence the number of reported episodes of sore throat or tonsillitis, but that a history of parental tonsillectomy and a family history of atopy have a positive association with the frequency with which children present with sore throat and tonsillitis.¹⁸ Parental enthusiasm for surgery varies. Some of the variation may be due to differences in demand for health care. There is evidence from the North of England and Scotland Study on Tonsillectomy and Adenoidectomy in Children (NESSTAC) that girls now present much more frequently than boys.¹⁹

Guidelines

The British Association of Otolaryngologists Head and Neck Surgeons (BAO-HNS or ENT-UK, www.ent-uk.org) has published a series of reviews under the title 'Clinical Effectiveness' to assist clinicians with decision-making for common clinical problems.²⁰ For tonsillectomy in children, the recommendations are in line with those of the Scottish Intercollegiate Guidance Network (www.sign.ac.uk).²¹

SIGN [**] suggest what are felt to be reasonable indications based on current level of knowledge, clinical observation in the field and the results of clinical audit of outcomes. Patients should meet all the following criteria:

- sore throats due to tonsillitis;
- five or more episodes of sore throat per year;
- symptoms for at least a year;
- episodes of disabling sore throat which prevent normal functioning.

As with any surgical procedure, the risks of surgery must be balanced against the potential benefit. Cognizance should be taken of whether the frequency of episodes is increasing or decreasing.

The American Academy of Otolaryngologists/Head and Neck Surgeons (AAO HNS) guidelines are widely accepted by US health care insurance companies. These guidelines¹⁰ suggest that tonsillectomy should be considered for children with 'three or more infections of tonsils and/or adenoids per year despite adequate medical therapy'.

The difficulties associated with implementing guidelines and the paucity of effect of guidelines on clinical practice are well known. There is evidence that the rate of ENT interventions is not significantly altered by the introduction of guidelines. This may not be the case with strictly imposed insurance company constraints such as are used in 'managed health care'. Moreover, when guidelines are broken, they tend to be broken more often in favour of offering rather than withholding surgery.²²

Health economics

Decision-making about the precise indications for tonsillectomy is complicated by the fact that each episode of tonsillitis may be treated individually and that there is a natural tendency for recurrent tonsillitis to improve with time. A relatively low cost but high volume procedure to alleviate a troublesome but nonlife-threatening condition, the operation has attracted the attention of those with an interest in the economics of health care. This in turn has focused on issues such as the value to the patient's health of removing the tonsils, the contribution of the operation to reduction of morbidity from illness and to the increase in productivity of the individual if a tendency to recurrent debilitating illness is abolished. In children, the focus is on quality of life for parent and child and the effect on the child's education.¹⁹ Tonsillitis is disruptive to school and family life, but tonsillectomy itself is associated with a period of morbidity. In uncomplicated cases, this usually involves at least two weeks absence from school with attendant implications for the parent or carer. Health-related quality of life indices and the economic aspects of sore throats in children have now been considered. A number of validated instruments evaluate benefit from childhood or adult ENT interventions, including

tonsillectomy. The results of evaluation of quality of life before and after the operation suggest that tonsil disease has a marked adverse effect on quality of life and that there is significant benefit from surgery.^{23, 24} [**]

TONSILLECTOMY TECHNIQUE

Introduction

Recent concerns about the risk of transmission of vCJD (see Tonsils and variant Creutzfeld-Jakob disease), the incidence of primary and secondary haemorrhage and the effect of surgical technique on complications post-tonsillectomy have been the subject of intense debate. The National Prospective Tonsillectomy Audit was established in 2003 on behalf of the Royal College of Surgeons of England and the BAO-HNS to look at some of these issues. Data were collected on over 50,000 patients undergoing tonsillectomy in England. Just under half were children (i.e. less than 15 years old). The results represent a comprehensive and up-to-date resumé of current practice and provide a firm basis for recommendations to clinicians particularly in relation to surgical techniques.²⁵

The optimal technique for removal of the tonsils must be as straightforward as possible for patient and surgeon. Given the frequency with which tonsil surgery is performed, it should be easy to teach, but above all it must be safe.²⁶

The traditional methods for removing the tonsils are the so-called 'cold steel' techniques using metal instruments. In recent years, perceived advantages in terms of reduced blood loss, less pain, more rapid healing and easier surgical technique have led to the introduction of several new methods.

'Cold steel' tonsillectomy

The most common method of 'cold steel' tonsillectomy is the dissection technique (Figure 96.2). In this, the tonsil is retracted medially, the mucosa overlying the tonsil capsule incised and the plane of loose areolar tissue between the tonsil and the pharyngeal musculature dissected with steel dissectors, gauze or cotton wool until the tonsil is fully mobilized (Figure 96.3). Blood vessels traversing the plane of dissection are dealt with either by ligature or diathermy as required. An alternative method of 'cold steel' tonsillectomy is the guillotine technique, whereby the tonsil is amputated using a specially designed guillotine device and haemostasis, secured as necessary by one of the above methods. Of these two techniques, traditional dissection remains the most frequently used. Arguably the advantage of speed in the guillotine technique is outweighed by the risk of leaving tonsil

Figure 96.2 Steps in dissection tonsillectomy.

Figure 96.3 Tonsillectomy set as used by one of the authors (RWC).

tissue behind. Blood loss during tonsillectomy can be considerable and may constitute over 10 percent of total circulating blood volume.²⁷

Cold steel dissection may be combined with diathermy to aid haemostasis, but many surgeons prefer ties or swabs. In the NPTA, the use of 'cold steel' dissection without diathermy was associated with the lowest haemorrhage rate. 'Haemorrhage' was defined as a bleed that prolonged the patient's hospital stay, required blood transfusion, a return to the operating theatre, or in the case of 'secondary' haemorrhage readmission to hospital. The haemorrhage rate for various techniques is shown in Table 96.1. The NPTA recommendation is that all trainee surgeons should become competent in cold steel dissection with ties before considering alternative techniques.

Diathermy tonsillectomy

In recent years, the technique has evolved of using diathermy not only as an aid to haemostasis when the

tonsil has been delivered, but to dissect the tonsil from its bed. This has the obvious advantage from the point of view of both operator and patient, particularly if a child, of reducing intraoperative blood loss to a minimum. Various claims and counterclaims have been made regarding the advantages and disadvantages of this technique, the most common alternative to traditional cold steel tonsillectomy. Major concerns about an increase in secondary haemorrhage rate with diathermy, following the introduction of disposable instruments for tonsillectomy during 2001, led to detailed retrospective audit of haemorrhage rates throughout the UK. This confirmed an incidence of secondary haemorrhage as high as 16.8 percent with diathermy in one published audit.²⁸ A Cochrane review of dissection versus diathermy for tonsillectomy found that only two of the studies that addressed this were sufficiently robust for analysis. These demonstrated reduced intraoperative bleeding but increased pain in the diathermy group, with no difference in secondary haemorrhage rate.²⁹ [**] These concerns were to the fore when the NPTA was set up. Surgeons use

a variety of diathermy techniques and specifications often based on individual preference and on what is available in a particular institution. Power settings vary and both bipolar and monopolar equipment is used. In the NPTA, postoperative bleeding was more frequent with diathermy

than with cold steel alone, (Table 96.1) and was particularly common with monopolar diathermy such that the authors recommended that surgeons using this method should consider changing. Table 96.2 lists the recommendations of the NPTA in full.

Table 96.1 Surgical techniques and primary and secondary postoperative haemorrhage rates.

Surgical technique (n = 33,921)	Primary tonsillar haemorrhage rate (%)	Secondary tonsillar haemorrhage rate (%)
Cold steel and ties/packs	0.8	1.0
Cold steel and monopolar diathermy	0.5	2.4
Cold steel and bipolar diathermy	0.5	2.3
Monopolar diathermy forceps	1.1	5.5
Bipolar diathermy forceps	0.4	4.3
Bipolar diathermy scissors	0.6	4.6
Coblation	1.0	3.6
Other	0.7	3.6

Reprinted from the National Prospective Tonsillectomy Audit, available on the Royal College of Surgeons of England website (www.rcseng.ac.uk), Table 4.6, with permission.

Table 96.2 Recommendations of the National Prospective Tonsillectomy Audit (2005).

- When a patient is counselled for surgery, the risk of tonsillectomy complications, and in particular postoperative haemorrhage, should be carefully explained to the patients/parents.
- This risk should be quantified, preferably using the surgeon's own (or department's) figures.
- National figures can be used, but this should be made clear to patients.
- Surgeons using monopolar diathermy should consider using an alternative technique. There are no advantages to using this instrument over other methods.
- All trainee surgeons should become competent in cold steel dissection and haemostasis using ties, before learning other techniques in tonsillectomy.
- Emphasis must be placed on teaching the correct use of, and the potential hazards of, diathermy and other 'hot' techniques. Checks should be made of the power settings before starting the operation.
- Inexperienced trainees must be supervised by a more senior surgeon until competency has been achieved. This recommendation is in agreement with the College's Standards on Good Surgical Practice issued in 2002.
- Irrespective of seniority and experience, surgeons who wish to start using new techniques, such as coblation, should undergo appropriate training.
- All ENT departments should have regular morbidity and mortality meetings to monitor adverse incidents affecting patient outcome. For tonsillectomy, data should be presented by the surgeon, indicating the technique used for dissection and haemostasis and power settings if applicable, type of instrument used, and any difficulties encountered.
- It is the responsibility of the surgeon, and if appropriate his trainer, to follow up any identified problems appropriately.
- Use of single-use instruments should also be recorded, especially for cold steel dissection.
- There is an urgent need for new standards for diathermy machines so that the amount of power used is obvious to the user. Manufacturers of diathermy machines should be encouraged to produce machines with information on the total amount of energy delivered to patients.
- Hospitals should encourage the use of machines that provide clear information on power settings.
- Manufacturers of single-use instruments should be encouraged to improve the quality of the instruments.
- There is a need for further laboratory and clinical research to investigate the influence of diathermy and other 'hot' techniques on an open wound, such as the tonsillar bed.
- In particular, there is a need to investigate the dose-response relationship between power used and complications.

Reprinted from the National Prospective Tonsillectomy Audit, available on the Royal College of Surgeons of England website (www.rcseng.ac.uk), page vii, with permission.

Coblation® tonsillectomy

This relies on the use of a specially designed bipolar electrical probe, which both coagulates and cuts the tissues as it develops the dissection plane between tonsil and capsule. The probes or 'wands' are single use and there is a cost consideration.

The technique involves the use of the operating microscope.^{30, 31} Coblation has gained widespread acceptance in the United States. Good results have been reported, but the technique seems to be highly operator-dependent. Postoperative bleed rates were unacceptably high in the NPTA. Some of these bleeds may reflect lack of familiarity with the technique; enthusiasts have reported bleed rates that are comparable with those obtained using cold-steel dissection. It is suggested that postoperative pain is less than with conventional dissection but one RCT has cast doubt on this and shown that morbidity was less with cold steel dissection.³² There are no good controlled studies comparing coblation with cold steel dissection without the addition of diathermy; current evidence is inadequate to justify its introduction in preference to cold steel dissection with ties and/or packs. The National Institute for Health and Clinical Excellence (NICE) advise that current evidence is sufficient to support the use of electrosurgery (diathermy and coblation) for tonsillectomy, but advise surgeons to ensure that they are appropriately trained and to make patients and parents/carers aware of the risk of haemorrhage after these techniques.³³

Ultrasonic dissection

Ultrasonic dissection uses an oscillating blade, which acts as both a cutting and coagulating device. Enthusiasts for the 'harmonic scalpel' have claimed advantages over conventional techniques,^{34, 35} in terms of reduced pain and general morbidity, but evidence remains unconvincing.

Laser tonsillectomy

With the advent of the laser as a surgical tool, the use of this method of dissecting out the tonsil has been advocated as having advantages in terms of reduction of bleeding, postoperative pain and more rapid healing. Several studies have failed to confirm these advantages. There is convincing evidence that the rate of secondary haemorrhage and late postoperative pain is significantly greater with laser.³⁶ [****] The evidence would suggest that this technique cannot be recommended as an alternative to conventional tonsillectomy on the grounds of cost, morbidity and safety.

'Capsulotomy' techniques

The above techniques are designed to remove the entire palatine tonsil. A preference for 'office-based' surgery particularly in the USA has led to the popularization of techniques to ablate a part of the tonsil, usually leaving the capsule intact. These 'tonsillotomy' techniques include thermal tissue ablation using radiofrequency volumetric reduction (RFVR) using a customized probe and surface laser surgery. They are widely used but have not been subject to good quality randomized controlled trials. They may be considered when tonsillectomy is undertaken in the very young where it may be desirable to leave some functioning lymphoid tissue.³⁷

MORBIDITY OF TONSILLECTOMY

Psychosocial morbidity and pain

Morbidity from the operation is significant. It includes both the expected adverse consequences and the possible complications. For most children it is their first experience of parental separation. Some show behaviour changes, such as attention seeking, temper tantrums and night waking. Depression and severe anxiety were commonplace but most units are now aware of the adverse consequences of separation and permit parents to accompany the child to the operating theatre and remain with him/her throughout the in-patient stay.^{38, 39} Pain and dysphagia are normal in the early postoperative period. Most children require at least a week to resume normal functioning and an average return to school or work time is one to two weeks.¹⁶ This is mainly due to pain preventing a return to normal diet and occasionally vomiting in the early postoperative period due either to the after-effects of the anaesthetic or to the effect of swallowed blood on the stomach. Much attention has focused in the literature on the management of these symptoms, one of the goals being early discharge from hospital.

Mortality

The complications of tonsillectomy may be divided into those associated with the anaesthetic and those directly associated with the operation itself. As the operation is normally performed on children and young otherwise fit adults, for the majority of patients the risk of the short anaesthetic required for tonsillectomy is small. There are risks inherent in anaesthesia in very young children and for this reason tonsillectomy is seldom performed in children before the age of two years, even in the unlikely event of them fulfilling the above criteria for consideration for surgery. In general, tonsillectomy is not frequently indicated in children under the age of four

years, the exception being children with obstructive sleep apnoea syndrome. There are some children who will be at increased risk from anaesthetic complications, principally related to the airway. These will include those with first and second branchial arch syndromes, Pierre–Robin sequence and Goldenhar syndrome and also those with Down syndrome, where airway compromise may occur. In the latter group, the additional hazard of atlantoaxial instability presents a further risk. Since its instigation in 1995, the Royal College of Surgeons in England audit on surgical mortality^{40, 41} records no deaths occurring from tonsillectomy, but there were two deaths reported in the British lay press in 2001. Extrapolating from US data⁴² and from Department of Health statistics, the potential mortality from tonsillectomy has been calculated at one per 24,000 operations²⁶ or one in 16,000 to one in 35,000.¹⁹

Perioperative complications

Occasionally, patients may experience temporomandibular joint dysfunction due to the mouth being opened too widely with the tonsillectomy gag. Small tears at the commissures of the mouth and cracks of the lip vermillion may be avoided by careful placement of the gag and the use of an emollient jelly on the lips prior to the commencement of surgery. Dissection outside the pharyngeal musculature may traumatize adjacent structures, such as the glossopharyngeal nerve, the pharyngeal venous plexus and the carotid sheath, but such events are extremely rare. Nontraumatic atlantoaxial subluxation (Grisel syndrome) may occur secondary to any inflammatory process in the upper neck. It is thought to be due to infection in the periodontoid vascular plexus that drains the region, bringing about paraspinal ligament laxity. It is described following both tonsillectomy and adenoidectomy. Treatment consists of cervical immobilization, analgesia and antibiotics to reduce the risk of neurological deficit.⁴³

Haemorrhage

The main early complication is haemorrhage. This is defined as primary (within the first 24 hours postoperatively) or secondary, i.e. occurring after 24 hours and during the phase of healing of the tonsil bed. The use of the term 'reactionary' is confusing. It is not uniformly defined in published work and its use is not advised. Data from the NPTA on haemorrhage have already been presented.

In a recent audit of 5646 tonsillectomy complications in Scotland in the years 2001 and 2002 (McKerrow, unpublished data), the rate of primary haemorrhage was quoted at 0.56 percent, rather lower than in some other published work and lower than that quoted in the NPTA. The readmission rate overall was 4.57 percent,

while 1.44 percent required return to theatre for arrest of haemorrhage. In other quoted series, the rate of 'secondary' haemorrhage has been as high as 16.8 percent. Secondary haemorrhage can occur any time until the tonsil bed has healed, which may take as long as two weeks. It is attributed – on sparse evidence – to infection in the granulating tonsil bed, often with streptococcal organisms. Antibiotic therapy with penicillin, pending bacteriological guidance is appropriate.

The reasons for this wide variation in bleed rates is not clear; it may be related both to the technique used and to the experience of the operator, although in the NPTA there was no significant difference in rates between trainees and more experienced surgeons.

Infection

Postoperative 'infection' is sometimes diagnosed in primary care. The presence of severe halitosis is the most prominent feature, usually associated with fever. It is almost certainly overdiagnosed as the appearance of the normally healing tonsil bed is of yellow/grey slough, which may give the impression of pus. Patients are routinely given advice to ensure a good intake of fluids and solids postoperatively on the grounds that this will clean the tonsil beds and avoid infection, but the evidence for this is scanty.

Late complications

Late complications are generally associated with the scarring that inevitably takes place as the tonsil bed heals. On rare occasions, this may result in impairment of palatal functioning with velopalatine insufficiency. Even more infrequent is the complication of nasopharyngeal stenosis, which very rarely occurs after adenotonsillectomy. Pharyngoplasty may be required to minimize the effects of these complications.

Concern has been raised about a possible increase in incidence of Hodgkin's lymphoma in adults who had tonsillectomy in childhood,⁴⁴ but a subsequent epidemiological study has not confirmed this.⁴⁵

PERIOPERATIVE MANAGEMENT

The main arms of management to minimize morbidity are skilled anaesthesia, analgesia and antiemetic therapy. There has also been interest in the use of steroid therapy pre- or postoperatively.

Anaesthesia

Strict protocols are frequently used in the United States, while in the UK the technique varies with the preference

of the individual anaesthetist. Total intravenous anaesthesia with propofol and remifentanyl is associated with fast 'wake up' and little 'hangover'. Propofol has the added merit of being an antiemetic agent. Deep inhalational intubation obviates the need for muscle relaxants, speeds reversal and avoids the use of potentially emetic agents, such as neostigmine. The total duration of anaesthesia should be as brief as is practicable, certainly less than 30 minutes.

Analgesia

Adequate analgesia is important in the immediate postoperative phase. Narcotics have a potent emetic effect and should be used with caution if at all. A single dose of narcotic may be administered in the recovery phase and codeine may be used in the early postoperative period, but subsequent to this, paracetamol is the drug of choice in the UK on the grounds of safety and efficacy. For some children this may not be adequate and a nonsteroidal antiinflammatory drug (NSAID) may be needed. There were concerns that the effect of these drugs on platelet adhesion might increase bleeding from the tonsil bed, but a recent metaanalysis found no such risk and a significant reduction in postoperative nausea and vomiting when compared with other analgesics notably narcotics.⁴⁶ [****] Aspirin should not be used in children because of the risk of Reye syndrome.

LOCAL ANAESTHESIA INFILTRATION

There has been recurring enthusiasm for the use of local anaesthetics infiltrated into the tonsil beds to reduce postoperative pain. The effect of injecting long- and short-acting local anaesthetics pre-, per- and post-operatively into the tonsil beds have all been studied. The results, including a Cochrane review, suggest that there is no current evidence of significant benefit from the use of these techniques and that further study is necessary.⁴⁷

Antiemetic drugs

Some patients suffer severely from vomiting post-operatively. In many cases this is related to swallowed blood irritating the stomach. In these cases, the symptoms usually settle after a single vomit of the stomach contents, but in those with prolonged vomiting parenteral antiemetic therapy may be indicated. Traditional antiemetics such as cyclizine and prochlorperazine may be adequate, but several studies suggest that the newer antiemetic ondansetron may have a useful role.⁴⁸ [****]

Steroid therapy

Peroperative glucocorticoids are widely used in the US but have gained less acceptance in the UK. A Cochrane review showed that a single intravenous dose of dexamethasone was an effective, relatively safe and inexpensive treatment for reducing morbidity from paediatric tonsillectomy.⁴⁹ [****] Dexamethasone has the added advantage of being an antiemetic. Many units use a single dose of 2–4 mg.

Antibiotics

A number of studies purport to assess the benefit of prophylactic antibiotics in minimizing postoperative morbidity. The very small reduction in time to resumption of normal activities apparent in some studies must be balanced against the potential side effects of antibiotics. Current evidence does not support their routine use.^{50, 51, 52} [****]

Day-case surgery

In recent years, there has been a trend towards encouraging day-case and in some areas '23-hour admission' tonsillectomy. The two main reasons for detaining post-tonsillectomy patients in hospital are safety with regard to haemorrhage and to manage morbidity from pain and vomiting.

The risk of primary bleeding diminishes to close to zero six hours after surgery so in theory the patient can be safely discharged at that time.⁵³ [**] In most centres this is done according to a strict protocol to ensure that the patient is adequately supervised in the home, has access to a telephone and reasonable proximity to hospital. Frequently a visit by an appropriately trained nurse on the first postoperative day is arranged. For this regime of management to prove satisfactory, adequate analgesia is essential. Although there is evidence that this mode of management is safe, there is considerable variation in its acceptability to parents and carers.⁵⁴ Currently, only a small proportion of tonsillectomies in England and Wales are done on a day-case basis (www.dh.gov.uk). The development of a successful and safe day-case tonsillectomy service requires the provision of a dedicated team of surgeon, anaesthetist, ward nurses and community back-up so that the issues of analgesia, antiemesis and safety can all be addressed adequately.⁵⁵

ALTERNATIVES TO SURGERY

The concept that tonsillectomy surgery might be avoided by some alternative management regime is attractive to

patients and health economists alike. Unfortunately this goal has proved elusive so far, but there are no conclusive studies that have looked at this issue in detail. There is no evidence that antibiotics will prevent recurrent tonsillitis.

The most commonly used approach is to manage each episode independently and to await natural remission of the recurrent problem. It is worth bearing in mind that lengthy and indiscriminate courses of antibiotics may not only contribute to the development of antibiotic-resistant organisms, but may also provoke allergic reactions to useful antibiotics and occasionally anaphylactic shock with a fatal outcome. Unpleasant side effects of broad-spectrum antibiotics, including vomiting and diarrhoea, are also frequent and relevant to the discussion. These issues are considered in more detail in Chapter 95, Diseases of the tonsil.

TONSILS AND VARIANT CREUTZFELD–JAKOB DISEASE

Variant Creutzfeld–Jakob disease is a rare, fatal neuro-degenerative disease. Histologically, it is characterized by intracellular vacuolation in nervous tissue, leading to a progressive spongiform encephalopathy. Tonsil biopsy is one of the methods of diagnosing vCJD and is less hazardous than brain biopsy, the main alternative. All possible precautions must be taken during this procedure to avoid any risk of cross infection and all equipment in direct contact with the patient must be destroyed by incineration. The biopsy material must be regarded as biohazardous and treated with appropriate precautions.

Some 150 cases have been identified since the disease was described in 1996. The causative agent is almost certainly the prion protein PrP which is also responsible for bovine spongiform encephalopathy (BSE). Involvement of the lymphoreticular system is a defining feature of vCJD and immunohistochemical accumulation of prion protein in the lymphoreticular system remains the only technique that has been shown to predict neurological disease reliably in animal prion disorders. During the overt clinical stages of the disease, tonsillar tissue is invariably infected with the prion. The infecting agent is thought to have entered the human food chain because beef was contaminated by feeding sheep offal to cows, a practice that became widespread in Britain in the 1970s. Cases of BSE in cattle were described from 1985 onwards and reached epidemic levels in 1992 (Bates, personal communication). Stringent controls in the beef industry now prevent contaminated meat from entering the food chain.⁵⁶

Nevertheless, there were concerns that the PrP might be present in the tonsils of ostensibly healthy individuals incubating the disease, or could have been present in those who had tonsillectomy during the long incubation

period (up to 20 years) when the prion may have been in the lymphoreticular system before the clinical features were manifest.⁵⁷ Poor quality preparatory techniques for tonsillectomy instruments may result in particulate matter remaining adherent to them. Normal sterilization methods do not destroy prions. Iatrogenic transmission of prion disease – but not vCJD – has been reported and this raised the possibility that prions could be passed from one patient to another on contaminated tonsillectomy instruments.⁵⁸

Transmission of vCJD has not been shown to occur in this way but the fear that it might do so led to the introduction of single-use instruments for tonsillectomy throughout the UK in early 2001. This policy was introduced by the Department of Health and the Chief Medical Officer. An improvement in the standards of decontamination of surgical equipment was held to reduce the risk of vCJD to acceptable levels, not so much by destroying the prion but by minimizing the amount of particulate matter (i.e. tissue) adhering to surgical instruments after cleaning. The perceived theoretical risk of prion transmission was very small and much less than the real risk of bleeding, thought to be increased by poor quality disposable instruments. Although the Department of Health rescinded the embargo on reusable tonsillectomy instruments in late 2001, single-use instruments continue to be used in Scotland and the issue remains controversial.⁵⁹ Uncertainties relate to the incubation period of vCJD, the size of the 'inoculum' which puts patients at risk of developing overt disease, whether transmission of prion is possible by direct contact with tonsillectomy instruments and whether prion introduced in this way causes systemic or central nervous system infection. There are continuing concerns about the adequacy of sterilization of equipment.

The prevalence of prion infection in the tonsils of healthy individuals is unknown. The National Anonymous Tonsil Archive (NATA) study, a large-scale screening programme of fresh tonsil tissue (www.hpa.org.uk), may clarify this, but despite the investment of significant resources in this project there are doubts that the power of the study will be adequate to give useful results. Other unknowns are whether healthy tissue can be inoculated with prion by direct transmission, whether direct contamination if it did occur in this way would result in disease, and what proportion of healthy individuals who have evidence of the prion in the tonsil tissue will go on to develop disease.⁶⁰

ACKNOWLEDGEMENTS

The authors would like to thank Professor Janet Wilson, Newcastle, for kindly reading the manuscript and commenting on it, and Grant Bates, Oxford, for assisting with the section on vCJD.

KEY POINTS

- Tonsillectomy is one of the most commonly performed surgical procedures in the developed world.
- The evidence-base for current practice is poor.
- Tonsillectomy rates vary considerably in different populations. These variations are not accounted for by variations in disease prevalence.
- Improvements following surgery are particularly small in less severely affected children. The morbidity of surgery usually outweighs any potential benefit in this group.
- There is no evidence that the benefits of tonsillectomy for recurrent sore throat are prolonged beyond two years.
- The operation is associated with significant morbidity, which may be minimized with careful perioperative management.

consider outcomes other than reduction in number of episodes of tonsillitis. The North of England and Scotland Study on Tonsillectomy and Adenoidectomy in Children should help provide a sound evidence-base to guide clinical practice.

- The morbidity of tonsillectomy remains significant. The optimal strategy for control of pain and emesis post-tonsillectomy still requires to be defined. The use of newer antiemetic agents and perioperative glucocorticoids seems set to increase.
- The risk, if any, of prion transmission by surgical instruments remains undefined and has important implications for all types of surgery. Work is necessary to quantify the risk and to take appropriate steps to minimize any hazard to patients. The National Anonymous Tonsil Archive currently being collated under the aegis of the Department of Health in England aims to collect data on the incidence of vCJD prion in normal tonsil tissue and may assist in quantifying the risks.

Best clinical practice

- ✓ 'Cold steel' dissection tonsillectomy is widely available and associated with the lowest postoperative haemorrhage rates in the hands of most surgeons. [Grade B]
- ✓ Surgeons in training must master traditional 'cold steel' dissection before considering alternative techniques. [Grade B]
- ✓ Adequate analgesia is essential in the postoperative care of children following tonsillectomy. [Grade D]
- ✓ Antiemetic agents, such as ondansetron, should be considered to reduce postoperative morbidity. [Grade D]
- ✓ There is now a sufficient body of evidence supporting the use of perioperative glucocorticoids to justify considering their use as routine. [Grade A]
- ✓ In secondary haemorrhage, surgery is rarely needed. Bleeding usually settles with antibiotic therapy alone. [Grade C]
- ✓ Continuing audit is essential; surgeons should familiarize themselves with the findings and recommendations of the NPTA. [Grade D]

Deficiencies in current knowledge and areas for future research

- High quality randomized controlled trials of tonsillectomy versus standardized conservative management are essential to define the optimal management of recurrent tonsillitis. The trials need to

SEARCH STRATEGY

Data for this chapter were obtained from the author's personal experience and bibliography, supported by a Medline search using the key words salivary gland, salivary disorders, sialolithiasis, congenital and child.

INTRODUCTION

Many of the salivary gland conditions that occur in children mirror those found in adults but relative incidences vary. In addition, there are some conditions that are unique to childhood. Salivary gland disease in children is uncommon. Clinical expertise in this area tends to be concentrated in the hands of a few; as a result the correct diagnosis may be overlooked and the primary management may be inappropriate.

CONGENITAL DISORDERS

Absence of salivary glands

Salivary gland agenesis or aplasia is extremely rare. If it involves all of the major salivary glands, the result is severe xerostomia with extensive dental caries. Partial agenesis may be missed as the remaining glands produce enough saliva to maintain the dentition. If in doubt, salivary tissue can be demonstrated by technetium 99m pertechnetate scanning, ideally augmented with magnetic

resonance imaging (MRI).¹ Treatment of xerostomia is supportive and is focussed on meticulous oral hygiene and the use of artificial saliva.²

Congenital salivary cysts

These are found most often in the parotid gland. They include cysts that occur in association with branchial cleft and branchial pouch anomalies (see Chapter 99, Branchial arch fistulae, thyroglossal duct anomalies and lymphangioma). They may present as intraglandular masses or with secondary sialadenitis due to ductal compression.³

Ductal anomalies

These are rare but include duplication and imperforate ducts. They may be demonstrated by contrast sialography but better still by MRI. If associated with secondary infection, they may require treatment. Marsupialization is usually adequate.³

Ectopic salivary tissue

Salivary acinar cell rests can be found as a focus of draining sinuses in the neck, the mandible and the cervical lymph nodes.³

INFLAMMATORY DISEASES

Viral parotitis (mumps)

A number of viruses, most typically mumps, may be implicated in acute sialadenitis. 'Mumps' is an acute infectious disease caused by the mumps virus, a paramyxovirus. Classically, children aged four to five are affected and 85 percent of cases occur below the age of 15 years. The incubation period is two to three weeks. Infection is spread by droplets from an infected person's respiratory tract. Mumps causes a mild pyrexial illness in up to 40 percent of infected patients with enlargement of one or more of the salivary glands, nearly always the parotid. Parotid involvement is typically bilateral. The diagnosis is confirmed by measuring viral titres for the S and V antigen. The S antigen is positive at presentation and persists for 12 months. The V antigen appears at one month but persists for up to two years.

No specific treatment is available and resolution is to be expected. Mumps may rarely be associated with severe complications, notably sensorineural deafness, orchitis, encephalitis and pancreatitis.

The use of mumps, measles and rubella (MMR) vaccine in 92 percent of developed countries has resulted in mumps becoming a rare disease in Western communities, where complications are now almost never seen. [***] There has been a recent increase in the incidence of mumps in Britain, presumably due to a reduction in the number of children given the MMR vaccine.^{4,5} Mumps deafness and encephalitis are still a significant global public health problem.⁶

Acute suppurative sialadenitis

Acute pyogenic infection of the salivary glands is characterized by painful swelling with erythema of the overlying skin. Organisms include *Staphylococcus aureus* and *Streptococcus viridans*. Dehydration and salivary calculi may be predisposing factors. Treatment is with antibiotics analgesia and adequate hydration. [*]

Acute parotitis of infancy

Acute pyogenic infection of the parotid gland in infancy is a distinct clinical entity. It occurs in the newborn and is more common in prematurity. The most likely organisms

are *S. aureus* and *Streptococcus pyogenes*, together with anaerobic bacteria. The affected gland becomes swollen and progresses to suppuration. The baby will be ill, pyrexial and reluctant to feed. Ultrasonography may help determine when frank pus is present. In the early stages, adequate doses of intravenous antibiotics may halt progression. Surgical drainage should be considered with extreme care due to the superficial position of the facial nerve in the newborn. Needle aspiration is safer than incision (Figure 97.1). [*]

Relapsing acute parotitis

This is the most common inflammatory disorder of the salivary glands in childhood. It is usually self-limiting and requires no surgery. [**]

PRESENTATION

Though recurrent parotitis may occur at any age, it most commonly presents at five to six years. The first episode is often diagnosed as mumps. Usually one, but occasionally both, parotid gland(s) will become acutely swollen and painful. The salivary flow from the duct is reduced and may be turbid. Episodes typically last a few days and may

© Hodder Arnold / Scott-Brown 7E

Figure 97.1 Acute suppurative parotitis in a baby aged three weeks.

be months apart. There may be some erythema of the skin overlying the gland. The child is usually afebrile. Although culture of the saliva is often sterile, the most common organisms are *Streptococcus pneumoniae* and *Haemophilus influenzae*.⁷

INVESTIGATION

Ultrasound examination of the affected gland will demonstrate any calculi or intraparotid abnormalities and is well tolerated by children.¹ Sialography is helpful in showing the changes of sialectasis that occur in most cases, but is difficult to perform in children (Figure 97.2). In any acute episode, a swab should be taken of the saliva from the duct of the affected gland, and if organisms are cultured appropriate antibiotic therapy should be given.

In any case of recurring infection it is important to consider the child's immune status, and to exclude diabetes mellitus, immunoglobulin deficiency and cystic fibrosis. The advice of a paediatrician should be sought if there is any doubt.

MANAGEMENT

In almost all cases, recurrent parotitis of childhood resolves by the age of puberty. [***] Therefore, management

is conservative in the expectation of reduction in the frequency and severity of attacks. Individual episodes should be managed by adequate hydration, analgesics and gentle external massage of the gland in the direction of the parotid duct towards its papilla to encourage drainage. Antibiotics are not indicated unless there is generalized malaise and fever. [*] If the attacks do not resolve, lavage of the parotid duct with normal saline after cannulation may reduce the frequency of the attacks. This can be undertaken under general anaesthetic if necessary.

There is little place for open parotid surgery. Even if irreversible structural changes in the gland have occurred, the condition is self-limiting and resolution of symptoms can be expected. If excision surgery is embarked upon, a subtotal parotidectomy will be required (Figure 97.3).⁸ [*]

GRANULOMATOUS DISEASES OF THE SALIVARY GLANDS

The most common granulomatous infections of the salivary glands are mycobacterial but this group of disorders includes rare infective conditions such as actinomycosis and cat-scratch disease. These conditions may simulate malignancy.

Mycobacterial infection of the salivary glands

This is probably not a true infection of the salivary glands but of the perisalivary lymph nodes in children. In Western communities, infection is more commonly by atypical or nontuberculous mycobacteria (NTM) than by *Mycobacterium tuberculosis*. [****] The most common organisms are *M. avium-intracellulare* complex, *M. kansasii* and *M. malmoense*. They can be identified with most certainty by culture in specialized reference laboratories.

Figure 97.2 Parotid sialogram showing the changes of sialectasis.

Figure 97.3 Chronic irreversible parotitis with salivary fistulae.

The condition of NTM salivary gland infection affects a young age group, typically three to four years old. The patients in the author's series ranged from one year nine months to seven years ten months, with an average of three years ten months.⁹

PRESENTATION

Patients present with a mass in the neck or face, usually painless and often with a short history. The overlying skin usually becomes discoloured with a violet hue. Early necrosis and breakdown of the tissues may occur. There is no facial nerve weakness in uncomplicated cases (Figure 97.4).

INVESTIGATION

The most important investigations are microscopy with Zeil Neilson staining, histology and culture of the affected tissue. Repeated culture of aspirated material may be negative. Fresh excised tissue is more likely to yield a diagnosis. It is important to inform the laboratory staff that the diagnosis is suspected before sending tissue.

While specific antigens for skin testing to the various mycobacteria are available, they are not easily obtained. They may be used as further evidence if the diagnosis is in doubt. All cases of suspected mycobacterial infection should have a Mantoux test and chest x-ray to exclude *M. tuberculosis*.

Imaging of the cervical mass is not particularly helpful. Ultrasound examination is often rendered difficult by the presence of skin necrosis.

Figure 97.4 Infection with atypical (nontuberculous) mycobacteria.

MANAGEMENT

Many cases of an enlarged cervical nodes infected by NTM will resolve spontaneously without necrosis. [***]

Where there is skin discoloration and early abscess formation, long-term treatment with anti-tuberculosis chemotherapy is usually administered. [**] A typical regime is ciprofloxacin 15 mg/kg/day as two doses and azithromycin 10 mg/kg/day over some months. In cases of necrosis or abscess formation, surgical excision of the inflammatory mass with preservation of the facial nerve is curative.¹⁰ [**] The organism is more easily grown from the excised tissue than from the pus. Simple drainage of an abscess may result in a chronically discharging fistula which can take 18–24 months to heal fully, with considerable scarring. [**] Coulter *et al.*¹¹ summarized the evidence base for current treatment regimes and concluded that there are no randomized controlled trials on which to base management strategies, but excision is curative and curettage is superior to incision and drainage. Single drug therapy rapidly induces resistance. Chemotherapy prior to surgery may help localize the lesion. Untreated the condition will spontaneously resolve over several years.

Sarcoidosis

Sarcoid is a chronic granulomatous condition of unknown aetiology. The onset of sarcoidosis is usually in early adult life but it can present in the teenage years. Parotid gland involvement is present in about 10 percent of cases and it may present acutely with fever and uveitis – Heerfordt's uveo-parotid fever. Facial palsy may occur in this condition. The changes in the gland are of noncaseating granulomata and may be demonstrated by biopsy of the minor salivary glands of the lower lip in 60 percent of cases.

Sjögren's syndrome

Sjögren's syndrome is an autoimmune multisystem inflammatory disorder which almost always involves the salivary glands (see Chapter 147, Non-neoplastic salivary gland diseases). In long-standing cases it is characterized by dryness of the oral and conjunctival membranes (Sicca syndrome). It is rare for a diagnosis of Sjögren's to be made in childhood but, when it is, the commonest presentation is with parotitis. Girls are more commonly affected than boys. Sicca syndrome is uncommon until adulthood. If suspected, rheumatoid factor, antinuclear antibodies and SS-A and SS-B autoantibodies should be measured.¹²

Treatment should be multidisciplinary with involvement of a paediatrician and dental surgeon. Lifelong surveillance may be needed as patients are prone to the development of lymphomata.¹³ [***]

HIV/AIDS

Salivary gland involvement in juvenile cases of HIV infection is more common than in adult disease and is referred to as HIV-associated salivary gland disease (HIV-SGD).

HIV-SGD

The main feature of HIV-SGD is the presence of lympho-epithelial cysts within the salivary glands, predominately the parotid. They are thought to be the result of hyperplasia of the intraglandular lymph nodes (Figure 97.5).

Confirmation of the cystic nature can be made on ultrasound scanning and, unless neoplasia is suspected, no surgical intervention is required. No virus is present in the cyst fluid.¹⁴ The finding of multiple parotid cysts in childhood should alert the clinician to the possible diagnosis of HIV infection.

Ranula

Ranula is the term to describe a cystic swelling arising in the floor of the mouth (ranula – L. frog). Ranula may be congenital or acquired and, on rare occasions, may be found in newborn infants.

AETIOLOGY

Ranula is the result of obstruction of one of the sublingual salivary glands. It is essentially a retention cyst. This may be spontaneous or may result from surgery to the floor of the mouth, especially submandibular duct relocation.

PRESENTATION

The ranula presents as a smooth cystic swelling under the tongue, usually to one side. It is often transparent or bluish in appearance with overlying small blood vessels. If

Figure 97.5 Lymphoepithelial cyst of the parotid gland in HIV infection.

large enough, it may affect both breathing and swallowing (Figure 97.6).

Plunging ranula

If extravasation of mucus occurs beyond the confines of the floor of the mouth through the mylohyoid muscle into the upper neck or submental region, a large cystic swelling develops. This can usually be defined on MR scanning but is difficult to clinically differentiate from cystic hygroma. Histologically, hygroma has a simple epithelial lining whereas a ranula is contained by loose connective tissue.

TREATMENT

Simple aspiration or drainage of a ranula results in a high recurrence rate. Both simple and plunging ranulas should be excised, together with the cyst wall and the sublingual gland. [**] Care must be taken to identify and preserve the lingual nerve which lies in close proximity. A ranula presenting in the neck will usually need an external approach for excision. Marsupialization of a plunging ranula is inadequate with a recurrence rate of 80 percent.¹⁵ Excision of the sublingual gland results in a low rate of recurrence.

Salivary gland stones

Salivary gland stones or calculi are rare in children. Stones are formed by crystal formation from salivary solutes, mainly hydroxyapatite. These salts can be precipitated out

Figure 97.6 Sublingual ranula.

of solution by a change in pH in the saliva or by dehydration. They are much more common in the submandibular gland than the parotid because of the mucoid nature of the submandibular saliva.

PRESENTATION

The stone will normally declare its presence by sudden enlargement of the affected salivary gland while the child is eating, caused by occlusion of the duct in the presence of salivary flow. The gland becomes swollen and painful and the swelling usually subsides over an hour or two. The stone may be visible or palpable within the duct. Parotid stones tend to be less calcified and therefore softer and less easy to feel. Sometimes, a large stone will be found coincidentally in the submandibular gland on routine radiology and may cause no symptoms.

INVESTIGATION

If the stone is clinically apparent, no further investigation is necessary. Plain x-rays may show a stone but intraoral views of the duct are preferable. If doubt persists, MR scanning is extremely sensitive in demonstrating calcium salts.

TREATMENT

If the stone is causing no symptoms, then it can be left alone. If the stone is accessible within the submandibular duct, it can be removed intraorally by making a linear incision in the floor of the mouth, extricating the stone and marsupializing the mucosal edges. Great care must be taken not to injure the lingual nerve which lies immediately deep to the duct. A stone within the substance of the submandibular gland which is causing persistent symptoms will necessitate excision of the gland. Endoscopy of the salivary ducts has been used to remove calculi but there is no account of this in children. Some radiologists report that a contrast sialogram may bring about improvement as the contrast flushes the debris from the gland.¹⁶ [*]

SALIVARY GLAND TUMOURS

Salivary gland tumours are extremely rare in children. They comprise vasoformative swellings, true neoplasms of salivary tissue origin and proliferative disorders of the perisalivary lymphoid tissue (lymphoma). For salivary gland tumours in adults see Chapter 189, Benign salivary gland tumours and Chapter 190, Malignant tumours of the salivary glands.

Vasoformative lesions

The commonest salivary gland swellings in childhood are vasoformative. While not truly salivary in origin, their management may require an extensive knowledge of

salivary gland anatomy and salivary gland surgery. It is important to distinguish between haemangioma and vascular malformation.

Haemangiomas are not present at birth but grow rapidly after birth. They are of endothelial origin and highly cellular. They initially grow rapidly for nine to twelve months and involution usually occurs by the age of three to five years. Most haemangiomas occur in the head and neck and many will involve the skin and the underlying salivary gland in the parotid region. Occasionally, the tumour may be deeply placed and lie within the parotid gland (Figure 97.7).

TREATMENT

Almost all haemangiomas will involute and surgery should be confined to management of bleeding or ulceration, or to cases where the diagnosis is in doubt. [*]

Diagnostic uncertainty in the case of an enlarging intraparotid mass may occasionally necessitate exploration and excision, with preservation of the facial nerve, even if haemangioma is suspected. High quality imaging has made this an extremely rare indication for surgery (Figure 97.8).

If the haemangioma is of such a size or position as to be life-threatening, treatment with steroids or α -interferon has been shown to be of benefit in hastening resolution. [**] Each is associated with significant potential morbidity in babies and should only be considered with extreme care. Steroids may be administered systemically or directly into the lesion. Pulse-dye laser therapy may be considered for ulcerating lesions; interferon is used systemically for its inhibitory effect on angiogenesis.¹⁷

Vascular anomalies are developmental malformations that are present at birth and enlarge slowly as the child grows. They may be venous, lymphatic or arteriovenous in origin and include cystic hygroma and lymphangioma (see Chapter 99, Branchial arch fistulae, thyroglossal duct anomalies and lymphangioma).

Salivary gland neoplasms

Neoplasms of the salivary gland account for 1 percent of all tumours in children. Fewer than 5 percent of all salivary tumours occur in patients under the age of 16 years. In the author's series of salivary gland tumours in childhood, a total of 14 neoplasms has now been treated, plus three lymphomas arising within the major salivary glands. Of these 14 cases, seven have been malignant and seven benign. Of these benign cases, only five were truly of salivary cell origin. The rarity of these tumours is such that inappropriate management frequently occurs before referral.¹⁸

PRESENTATION

Salivary gland tumours in children present as an enlarging mass. Growth is usually slow, and rapid growth is more suggestive of lymphoma arising in an intraglandular lymph node. They are usually painless. Facial nerve palsy at presentation is indicative of malignancy. Eighty percent of all salivary neoplasms occur within the parotid gland.

Benign tumours

The commonest benign tumour encountered is pleomorphic salivary adenoma (PSA) accounting for approximately 30 percent of all paediatric salivary neoplasms. The majority occur within the parotid gland but they may

Figure 97.9 Pleomorphic adenoma of the submandibular salivary gland.

also occur in the submandibular gland or in extra glandular sites (Figure 97.9).

In a large series from the Mayo clinic of salivary neoplasms in children, the only benign salivary neoplasm encountered was PSA,¹⁹ but all types found in adults do occasionally present.

TREATMENT

The treatment of benign salivary tumours is as it is in adults, by wide excision and facial nerve preservation. [**] The relatively superficial position of the facial nerve in children must be considered when performing parotidectomy. Particular care must be taken to achieve good surgical margins and avoid rupture of the tumour, since adjuvant radiotherapy cannot be safely used in children to salvage an unsatisfactory surgical procedure. Scar hypertrophy is more common in children than in adults, but in the author's practice the incidence of Frey's syndrome after parotidectomy is less.

Malignant tumours

The relative proportion of salivary tumours in children which prove to be malignant is higher in children than in adults, though of course overall, salivary neoplasms in children are extremely rare. In most series approximately half are malignant.

Most malignant salivary gland neoplasms in childhood present simply as an enlarging mass. Growth may be slow and there is usually no other evidence of malignancy.

Facial weakness and increasing pain are strong indications of malignant disease.

PATHOLOGY

Most series show that the most common salivary malignancy in a paediatric age group is mucoepidermoid

carcinoma (approximately 50 percent) followed by acinic cell carcinoma (20 percent).

More aggressive tumours such as adenoid cystic carcinoma and adenocarcinoma may also occur (Figure 97.10).

INVESTIGATION

All cases of salivary gland neoplasm in children should be treated as potentially malignant. [*] Aspiration (needle) biopsy and cytology are of limited value. In children this will usually require general anaesthetic and assessment of salivary gland histology is notoriously difficult. Ultrasonic imaging of the salivary mass is easy to perform, noninvasive and well tolerated by children. It gives information about the location and size of the lesion and will indicate whether it is cystic or solid. CT and MR may be needed, including imaging of the chest.

MANAGEMENT AND TREATMENT OF MALIGNANT TUMOURS

Management will involve a multidisciplinary approach with input from a paediatric oncologist and his/her team. These children and their families are best treated in a

designated centre where the whole range of support services for children with cancer is available.

As with benign neoplasms, wide surgical excision is required for malignant tumours. Usually, the diagnosis cannot be made preoperatively unless there is associated facial palsy. It is essential to counsel the child and parents carefully prior to operation regarding the possible need for facial nerve sacrifice.

The surgical margins on the specimen must be marked and evaluated by the pathologist and adequacy of excision confirmed. Provided the excision margins are satisfactory, no adjuvant treatment is indicated. [**] The author's series has shown only one recurrence, that of an acinic cell tumour after four years, with subsequent freedom from relapse after ten years.

The Mayo clinic series shows only one recurrence out of 14 malignant cases who had their primary treatment at the Mayo. The recurrence rate was higher in cases referred after initial treatment in a nonspecialist centre.¹⁹ [**]

Adjunctive radiotherapy and chemotherapy are reserved either for recurrent disease or very aggressive disease at the time of the initial surgery and should be determined with the collaboration of a paediatric oncologist. Long-term follow-up is essential in these rare cases.

Figure 97.10 Mucoepidermoid carcinoma of the parotid gland.

KEY POINTS

- The relatively superficial position of the facial nerve should be constantly borne in mind when contemplating surgery in the parotid region in children.
- Consider NTM in a child with a discharging lesion in the parotid region.
- Relapsing parotitis is almost always self-limiting and resolves at puberty.
- The rarity of salivary tumours in children is such that treatment should only be in specialist centres.

Best clinical practice

- ✓ Treatment of acute suppurative parotitis is with analgesics hydration and antibiotics. Surgery is rarely indicated. [Grade C]
- ✓ Relapsing parotitis is almost always self-limiting and resolves at puberty. [Grade C]
- ✓ Consider NTM in a child with a discharging lesion in the parotid region. [Grade C]
- ✓ The traditional advice that a ranula can be adequately treated by simple marsupialization should be revised. These swellings are best excised. [Grade C]

- ✓ The finding of multiple parotid cysts in childhood should alert the clinician to the possible diagnosis of HIV infection. [Grade B]
- ✓ Almost all haemangiomas will involute and surgery is rarely needed. [Grade B]
- ✓ Salivary tumours in children are rare but a higher proportion are malignant than in adults. [Grade C]

Deficiencies in current knowledge and areas for future research

- The implementation of vaccination programmes throughout the developing world would greatly reduce the morbidity of mumps encephalitis and deafness.
- The epidemiology of NTM and the reasons for the recent increased incidence in Western communities may become clear.
- The respective roles of surgery and chemotherapy in the management of NTM may become better established.
- Salivary gland neoplasms are so rare that randomized controlled studies may not be possible; a national register of these tumours and treatment only in centres where adequate expertise is available would improve outcome.

SEARCH STRATEGY

Systematic reviews were identified using the key words: childhood cancer, head and neck, thyroid cancer, rhabdomyosarcoma, nasopharyngeal carcinoma, neuroblastoma, lymphadenopathy, Hodgkin's lymphoma, non-Hodgkin's lymphoma, sarcoma, palliative care; and subject headings in the Cochrane database of systematic reviews. Individual articles were then identified using the same search terms in Ovid Medline. A hand-search of the ensuing bibliographies completed the search.

INTRODUCTION

This chapter will focus on the epidemiology of childhood cancers of the head and neck region and the general principles of assessing and managing malignancy in paediatric patients. It will then discuss the more common histological types individually. The long-term sequelae of treatment in survivors, palliative care and future developments will be addressed.

EPIDEMIOLOGY

After trauma, cancer is the most common cause of death in childhood. Approximately one-third of childhood malignancies are leukaemias, 25 percent are brain and spinal tumours, 15 percent are embryonal (neuroblastoma, retinoblastoma, Wilm's tumour and hepatoblastoma) and 11 percent are lymphomas. The remainder are bone and soft tissue sarcomas and miscellaneous

tumours (see below under Miscellaneous tumours). Up to 12 percent of primary childhood malignancies originate in the head and neck area and so may present to the otolaryngologist. Lymphoma is the most common diagnosis in all series, followed by thyroid and neural tumours. Sarcomas and salivary gland tumours are less common and squamous cell carcinomas are rare.¹ The distribution of histological types varies greatly depending on the age and sex of the child with neuroblastoma the most common in infants and thyroid carcinoma the most common malignancy in adolescent females. There is a bimodal age distribution of malignancy in children. The most common age group affected is 15 to 18 year olds, closely followed by the under fours.^{1, 2}

Cancer data from many parts of the world have suggested a small but steady recent increase in cancer rates in the under 19s. This increase would appear to be more marked in head and neck malignancies.¹ This elevation in numbers may in part be due to improved data collection. In parallel, the consistent use of effective

multimodality treatments, including combination chemotherapy, surgery and radiotherapy, has resulted in a significant improvement in prognosis. A study from the UK observed five-year survival rates improving from 42 percent (diagnosis made between 1968 and 1977) to 71 percent (diagnosis made between 1988 and 1995).³ Early recognition is therefore important as treatment is becoming increasingly effective in reducing the mortality in childhood malignancy.^{4,5}

It is thought that only around 5 percent of malignancies in childhood are inherited. The underlying aetiology of the noninherited types remains unclear but certain chemotherapeutic agents, viruses (e.g. Epstein–Barr) and irradiation are known to play a role. Other potential carcinogens are suspected but not proven (pollution, parental exposure to toxins, electromagnetic fields).^{1,6}

PRESENTATION AND ASSESSMENT

The most common presentation of a malignancy in the head and neck region in childhood is the **asymptomatic mass**. **Otalgia, rhinorrhoea, otorrhoea and nasal obstruction** may be present in both benign and malignant

disease. More worrying symptoms would include **stridor, dysphagia and haemoptysis**.⁷ Reactive lymphadenopathy in children is extremely common and gives rise to frequent therapeutic dilemmas. Studies have suggested that the best predictors of malignancy in cervical lymphadenopathy are the size of the node, the number of sites involved and the age of the patient. Other concerning features would be lymphadenopathy in the supraclavicular region, an associated abnormal chest x-ray or fixed lymph nodes.^{8,9} [**/*]

Examination would involve a complete assessment of the head and neck region and systemic evaluation with particular regard to the presence of lymphadenopathy elsewhere and the presence or absence of abdominal masses. Flexible nasendoscopy is possible in many children (**Figure 98.1**). Imaging with the help of a paediatric radiologist can often obviate the need for biopsy. However, full assessment of a mass may require examination under anaesthetic with biopsy.

Biopsy

Fine needle aspirate (FNA), sometimes referred to as aspiration biopsy cytology (ABC), **has a more limited role**

Figure 98.1 Flexible nasendoscopy under local anaesthetic in the clinic setting.

to play in the child than the adult. Young patients may simply not tolerate this method of biopsy. With particular regard to cervical lymphadenopathy, the most likely neoplastic diagnosis is lymphoma and at the present time it is recognized that excision biopsy is the best method of confirming and typing this histologically.^{10, 11} FNA, often under ultrasound control, can be useful in the assessment of thyroid and salivary gland lesions and these tumours often present in older children who may tolerate such intervention. [**/*]

Imaging

Ultrasonography, CT and MR scanning can all have their part to play in further assessment. Imaging of the neck is more accurate than clinical examination in detecting lymphadenopathy. CT and MR scanning may require a general anaesthetic in a younger child and it is helpful to discuss the available imaging options with a paediatric radiologist prior to proceeding, to avoid unnecessary and additional anaesthetics. Positron emission tomography (PET) scanning is also becoming increasingly used in the assessment of neoplastic lesions in the head and neck in children, but is not readily available at the present time in most departments.⁷

THE CHILD WITH CANCER

The history and subsequent investigations of a child presenting with a suspicious lesion of the head and neck region must be tailored to the age and maturity of the child. In most situations, when the child is old enough, he or she should be included in any discussion about investigations and treatment and they should also be involved in consent for any procedures required.

The diagnosis of cancer in a child has a tremendous impact not only on the patient, but also on parents, siblings, other family members and friends. Immediate involvement of a specialist paediatric multidisciplinary oncology team is mandatory. An open and realistic approach should include an explanation of what to expect from the investigations and treatment, the side effects and some idea of prognosis. This is vital in maintaining trusting relationships with the child and his or her family, in reducing uncertainty, preventing inappropriate hope and allowing proportionate adjustment.

Parents may feel guilty that they waited too long before seeking medical advice. They may be concerned that they have, in some way, caused their child's cancer. They can also feel guilty about making their child go through a series of invasive investigations and radical treatments. This can put an immense strain on the parents' relationship with each other and with other family members and friends, not least the child involved. Also, siblings of the affected child may resent the additional time and

attention that their sick brother or sister receives. Support services are therefore vital in reassuring and supporting all the individuals concerned.

The amount of information that any child will require regarding their illness depends to some extent on the age and maturity of that individual. Most children aged six or more (and some more mature younger children) need to know their illness has a name and what that name is. All children require an explanation of the procedures to be performed and reassurance that any intervention is not a 'punishment'. In children between the ages of six and eleven, these procedures and side effects of treatment may provoke much more anxiety than the illness itself. For example, loss of hair or a limb seem much more real and distressing than the prospect of death. Alterations in physical appearance can cause great insecurity in a child or adolescent, resulting in isolation and poor self-esteem. Children aged around 11 and over will have fears surrounding the diagnosis and its prognostic implications in addition to the above. Children should be encouraged to talk about their feelings or, if they are too young, they can express themselves in drawings or play.¹¹

ONCOLOGY SERVICES

In the UK, as in many other parts of the world, the importance of centralization of paediatric cancer services is recognized.⁴ This enables care to be provided by highly trained and specialist paediatric oncologists and allied staff, and facilitates the progress of research. In Britain, there are 22 United Kingdom Children with Cancer Study Group (UK-CCSG) centres. Working in conjunction with the medical staff are social workers, nurses, dieticians, psychologists and other health care professionals in order to provide comprehensive support for children and their families. The emphasis on centralization of paediatric oncology services, the sharing of data and the establishment of international working groups has resulted in the publication of a number of treatment protocols that are widely used in the management of children with cancer.

The practicalities of investigating and treating children with cancer provide some particular challenges. Venous access for blood sampling and to administer chemotherapeutic agents can be difficult, and indwelling venous catheters are usually inserted at an early stage. Radiotherapy may require general anaesthesia in younger patients to ensure that the child remains still during irradiation. Other interventions (e.g. lumbar puncture and intrathecal injection) may also require general anaesthesia. Children tolerate the immediate side effects of chemotherapy and radiotherapy much better than adults but the long-term sequelae of such interventions can have a very significant effect on the health of childhood cancer survivors (see below under Long-term sequelae of treatment).

THE MORE COMMON CHILDHOOD CANCERS

Lymphoma

Cervical lymphadenopathy in childhood is common and although the huge majority of cases will be due to reactive hyperplasia, it may be necessary to exclude malignancy. Lymph nodes in the neck larger than 2 cm are unusual in childhood and systemic symptoms such as weight loss, fever and organomegaly are usually indicators of serious pathology.⁸ FNA has a limited role and excision biopsy will provide the diagnosis.¹² [**]

Lymphomas are malignant neoplasms of the lymphoreticular system. Most lymphomas of the head and neck region in the paediatric age group present with enlarged cervical lymph nodes.

Hodgkin's lymphoma

This is distinguished morphologically by the presence of Reed Sternberg cells which are large and multinucleated with abundant cytoplasm. There are several classifications but the universally accepted one is the Rye classification. Within this there are four subtypes: lymphocyte predominant (LP), mixed cellularity (ML), lymphocytic depleted (LD) and nodular sclerosing (NS). NS is the most common type found in children and young adults. It has the propensity to involve the lower cervical, supraclavicular and mediastinal lymph node groups.

No definitive causal factors have been identified but there is an association with previous infection with Epstein–Barr virus.¹³

Hodgkin's lymphoma most commonly presents with lymphadenopathy in the neck and two-thirds of all children will have mediastinal lymphadenopathy at presentation. It rarely occurs under the age of five and there is a male predominance. 'Constitutional' upsets such as fever, night sweats and weight loss are present in 25 to 30 percent and this is associated with a poorer prognosis.⁷

Following careful examination and biopsy confirmation, the diagnostic workup of a child with Hodgkin's disease (following thorough examination and biopsy confirmation) would include a chest x-ray, routine blood tests (although abnormal results are usually nonspecific) and staging scans (CT chest and MRI abdomen). Recently, PET scanning has become a routine part of staging and of assessing effectiveness of treatment. There is no longer a place for staging laparotomies. Bone marrow biopsy and bone scan are only indicated in children with more advanced disease.¹⁴ Currently, the Ann Arbor staging classification is used for Hodgkin's disease (see Chapter 22, Haemato-oncology).

Treatment depends on the age and physical maturity of the patient, the disease stage and bulk and the potential

treatment sequelae. In the paediatric population, the trend is to treat in multimodality fashion so as to reduce the morbidity and mortality associated with high doses of chemotherapy or radiation therapy needed for single modality treatment. Disease-free survival is over 90 percent in many series.¹⁵ Those children with intermediate risk of disease (constitutional symptoms, bulky disease or spleen involvement) may require an increased number of cycles of chemotherapy and an increased dose or volume of radiation therapy. In advanced disease, combined chemoradiotherapy is the treatment of choice. LP Hodgkin's disease is associated with a better prognosis and separate shorter and less intense treatment protocols are implemented. The regimens used in the treatment of Hodgkin's disease contain substantial doses of alkylating agents which are associated with the potential for significant morbidity.¹³ [***/**]

Haematopoietic stem cell transplantation can be implemented in those children who relapse, but the risk of transplant-associated morbidity and mortality is not insignificant.¹³

Non-Hodgkin's lymphoma

Approximately 60 percent of paediatric lymphomas are non-Hodgkin's lymphomas (NHL). There is a male predominance. The low grade, relatively indolent NHLs seen in adults are exceedingly rare in children. Paediatric NHLs tend to be aggressive with a propensity for widespread dissemination and half of these are small cell lymphomas (Burkitt's and Burkitt's-like). The classification of NHL is confusing and controversial but paediatric NHLs are usually divided into three main histological categories. These are lymphoblastic lymphoma (predominantly of T cell origin), small noncleaved cell lymphoma (Burkitt's and non-Burkitt's subtype of B cell origin) and large cell lymphoma (B or T cell origin).¹⁶ The Revised European American Lymphoma (REAL) classification is used in paediatric NHL and is a useful guide to management and prognosis of NHL.

The relative frequency and incidence of NHL varies quite markedly from country to country. In equatorial Africa, Burkitt's lymphoma accounts for approximately 50 percent of childhood cancers. In Europe and the US, approximately one-third are lymphoblastic lymphomas, one-third are Burkitt's and Burkitt's-like lymphoma and the rest are predominantly large cell lymphoma. In some parts of the world, an extremely high number of these tumours are positive for Epstein–Barr virus (EBV), e.g. parts of Africa. In contrast, the percentage of tumour positive for EBV in the US is much smaller. There is an increased incidence of NHL in association with immunosuppression and congenital and acquired immunodeficiency.¹⁶

All childhood NHLs are rapidly growing neoplasms and a significant number of children will have widespread

disease at the time of diagnosis, which may involve the bone marrow, central nervous system or both. Involvement of extranodal sites, especially Waldeyer's ring, is particularly common in children. Lymphadenopathy occurs in 50–80 percent of all patients and 45 percent have cervical lymphadenopathy at the time of presentation. Bone marrow involvement is not infrequent and the replacement of more than 25 percent of the bone marrow by tumour cells is usually assigned a diagnosis of acute lymphoblastic leukaemia. Children with endemic Burkitt's lymphoma frequently present with involvement of the jaw and this is particularly common in the younger age group.¹⁶

DIAGNOSIS AND STAGING

Because NHLs in children progress more rapidly, a speedy diagnosis is extremely important. A biopsy will provide tissue for histological confirmation and surgery then has little further role to play. Staging investigations will follow and will include relevant blood tests (full blood count, urea and electrolytes and liver function tests – lactic dehydrogenase (LDH) is a useful marker of disease – bone marrow biopsy and cerebrospinal fluid (CSF) examination. Staging laparotomy is not advocated in patients with NHL and ultrasonography, CT (chest) and MR (abdomen) scanning are used in assessing spread.¹⁶ The Ann Arbor staging classification can be applied to NHL (see Chapter 22, Haematology).

TREATMENT

The treatment of choice in childhood NHL is multiagent chemotherapy. The rapid doubling time of high grade NHL makes it particularly chemosensitive. Chemotherapeutic regimens vary depending on the histological classification of the disease. Radiation therapy has a limited role in NHL and is generally reserved for selected anatomical sites such as the cranium where a child has overt central nervous system (CNS) disease. CNS prophylaxis in children with high grade NHL can be achieved with intrathecally administered chemotherapy.^{14, 16} [***/**]

PROGNOSIS

Long-term event-free survival (EFS) is excellent in lymphoblastic lymphomas. It ranges from 80 to 90 percent in patients with limited disease and from 65 to 80 percent in patients with advanced disease. In Burkitt's, where chemotherapeutic regimes are more intense and shorter, the long-term EFS ranges from 90 to 100 percent in patients with limited disease to 75 to 85 percent with extensive disease. Even in patients with extensive bone marrow disease, the EFS is improving. Large cell lymphomas are more of a challenge to treat

because of their biological heterogeneity and long-term EFS ranges from 50 to 70 percent.^{14, 16} [***/**]

Patients who relapse after receiving dose-intensive multiagent chemotherapy have an extremely poor prognosis. These patients are treated with high-dose chemotherapy regimes with or without bone marrow transplantation or would be candidates for drugs in phase II trials.

Rhabdomyosarcoma

Rhabdomyosarcomas account for up to 60 percent of all sarcomas in the paediatric population and 40 percent occur in the head and neck region. Nearly half of these tumours occur in children under the age of five.⁴ The prognosis for this tumour used to be extremely poor but over the last 30 years survival rates have increased dramatically, particularly with the introduction of multimodality therapy in which surgery, multiagent chemotherapy and radiotherapy have been combined.¹⁷

Histologically, rhabdomyosarcomas resemble normal foetal skeletal muscle before innervation. Two types are identified and these are embryonal (good prognosis) and alveolar (poor prognosis). The alveolar type is found in older children and is often associated with metastatic spread. It is less common than the embryonal type.^{18, 19}

PRESENTATION

Rhabdomyosarcomas of the head and neck occur most frequently in the orbit or parameningeal sites and these include the paranasal sinuses, nose, nasopharynx and middle ear. The most common presenting symptoms are pain and swelling. Paranasal rhabdomyosarcoma may present with a gradual onset of nasal obstruction and bloody nasal discharge. Tumours within the ear may present with symptoms of bloody discharge and persistent otalgia, despite treatment. A polypoid mass may be visible in the ear canal or nasal cavity.¹⁹ The reported incidence of lymph node involvement varies between 3 and 36 percent.¹⁸ Metastases occur by both haematogenous and lymphatic spread.

ASSESSMENT

Assessment should include a thorough examination of the upper respiratory tract and head and neck region including the cranial nerves. Flexible nasendoscopy may be employed in the clinic. An MR scan should be performed to evaluate the primary lesion and to rule out metastatic disease (Figure 98.2). A CT scan may be a useful complementary tool, particularly in the paranasal sinuses and skull base, to determine bony erosion and it is the best method to assess the chest. Bone marrow examination should also be performed. The Inter Group

Figure 98.2 Paramedian T1-weighted MR scan through the left orbit of a three-month-old boy. There is a huge mass of rhabdomyosarcoma in the anterior orbit (short arrow) displacing the globe and submandibular lymphadenopathy (long arrow).

Table 98.1 Staging of rhabdomyosarcoma according to the IRS. (Inter Group Rhabdomyosarcoma Study)

Staging of rhabdomyosarcoma	
Group I	Localized disease completely resected. No regional nodes Confined to muscle or organ of origin Contiguous infiltration outside muscle or organ of origin
Group II	Localized disease with microscopic residual disease or regional disease with no residual or with microscopic residual disease Grossly resected with microscopic residual disease (nodes negative) Regional tumour completely resected Regional nodes grossly resected but evidence of microscopic residual disease
Group III	Incomplete resection or biopsy with gross residual disease
Group IV	Metastatic disease present at onset

Rhabdomyosarcoma (IRS) study recommends the clinical staging shown in **Table 98.1**. The majority of children are stage II at the time of assessment²⁰ as it is rarely possible to completely excise these tumours.

TREATMENT AND PROGNOSIS

Since the establishment of the IRS Study Committee in 1972, protocols have been developed and are now widely adhered to. A multimodality approach has been adopted. In general, the role of surgery today is to simply evaluate the extent of the lesion and biopsy the tumour. Occasionally, when the rhabdomyosarcoma is an easily accessible polypoid lesion, then wide surgical removal may be appropriate. A debulking procedure may also be useful. Sophisticated skull base surgery can now be implemented in areas that were previously thought to be inaccessible.¹⁹ Multiagent chemotherapy and radiotherapy are then implemented as appropriate. [**/*]

Prior to 1960, approximately 10 percent of patients survived five years. Now the prognosis is excellent in patients with early tumours (over 80 percent survival). With more advanced tumours the prognosis is still relatively poor and in those with meningeal involvement the five-year survival is less than 10 percent. Although nodal metastases at initial presentation are not correlated with an unfavourable prognosis, development of nodes during follow-up does imply a poor outlook.^{19, 20, 21} [**/*]

Thyroid carcinoma

Thyroid carcinoma in the paediatric population is uncommon. In the US there are five new cases per million per year. It is much more common in adolescents than in younger children and is also much more common in females with a ratio of 4:1. Approximately 45 percent of these lesions in children will be differentiated papillary carcinomas with a further 45 percent of mixed papillary/follicular types with only 10 percent being follicular lesions.²² Medullary thyroid carcinoma (MTC) is rare (only 10 percent of thyroid malignancies in children) and must be suspected in children with multiple endocrine neoplasia (MEN) types IIa and IIb (see under Medullary thyroid carcinoma). Anaplastic and undifferentiated tumours are extremely rare in children and adolescents.

AETIOLOGY

A clear relationship has been established between the development of thyroid carcinoma and previous irradiation. In one study, as many as 17 percent of patients had previously received irradiation to the neck.²³

PRESENTATION

Patients usually present with an asymptomatic solitary mass in the anterior or lateral neck. At presentation, there is often regional lymph node involvement (74 percent) and distant parenchymal metastases (25 percent).²²

INVESTIGATIONS

Investigations will include an ultrasound scan, usually in conjunction with an ultrasound-guided FNA. Regional and distant metastases can be assessed with a chest x-ray and CT scan. Thyroid function tests and plasma thyroglobulin levels should be obtained and also plasma calcitonin where a diagnosis of medullary carcinoma is suspected.

TREATMENT

Controversy remains over the optimum treatment in differentiated thyroid carcinoma in children because the long-term mortality in these patients is low and serious operative and postoperative complications can occur following radical surgery. These include recurrent laryngeal nerve damage, hypocalcaemia and airway obstruction requiring tracheostomy.²² It has become clear that these tumours in children are slow-growing and associated with prolonged survival rates, even in the presence of extensive disease. Some authors maintain that an aggressive approach is mandatory^{24,25} while others have adopted a more conservative approach with the use of lobectomy and subtotal thyroidectomy for small and isolated lesions.^{22,23,26}

Ideally, treatment should include complete surgical excision if possible. Total or subtotal thyroidectomy should be performed if adjuvant radioiodine treatment is planned. Following surgery, a whole-body radioiodine scan is performed and ablative radioiodide treatment given if necessary. Plasma thyroglobulin can then be used as a tumour marker and suppressive levothyroxine should be given. Radiotherapy is rarely indicated in differentiated thyroid carcinoma in childhood.⁷

PROGNOSIS

A long-term study of 329 patients under the age of 21 confirmed only eight deaths over a long period of time and of these only two were disease related. The risk of progression of disease was more common in younger patients and those with residual cervical disease after definitive thyroidectomy. The majority of recurrences are in cervical lymph nodes or thyroid bed (54 percent), or lungs (16 percent).²⁶ The majority of relapses occur within the first seven years but have been seen as long as 25 years after treatment.²²

Medullary thyroid carcinoma

The detection of MTC in younger children is usually made following screening in 'high risk' individuals who have a family history of MEN 2.⁷ This is confirmed by elevated baseline levels of calcitonin or screening for the Ret (rearranged during transfection) protooncogene

on chromosome 10. If positive, the child should be considered for prophylactic total thyroidectomy.⁷ See Chapter 197, Thyroid cancer.

Nasopharyngeal carcinoma

In the US and Europe, nasopharyngeal carcinoma (NPC) is an uncommon tumour comprising only 1–2 percent of paediatric malignancies, but in other geographical locations, such as parts of Africa, 10–20 percent of childhood malignancies are due to NPC. There is a bimodal age distribution of this disease with an early peak of 10 to 20 years and a second peak between 40 and 60 years. NPC is one of few malignant tumours in childhood that emerges from the epithelium and there is an association with EBV. Males are twice as likely as females to develop NPC. Children with NPC almost invariably have the undifferentiated variant that is associated with higher rates of advanced locoregional disease and distant metastases.²⁷ Despite this, the five year disease-free survival is not significantly different to that of adults at 30–60 percent.²⁸

PRESENTATION

Children may present with a cervical mass secondary to lymph node metastases. Other presenting symptoms and signs may include nasal congestion, epistaxis, otitis media with effusion, otalgia and cranial nerve palsy. As many as two-thirds of children with NPC have metastatic disease in the neck at presentation. Delay in the diagnosis occurs frequently because many of its symptoms mimic those of an upper respiratory tract infection.

ASSESSMENT

Nasopharyngeal examination and biopsy is required for tissue diagnosis. CT or MR scanning allows precise evaluation of the primary tumour and confirmation of the presence or absence of metastases, most particularly in the neck. The American Joint Committee in Cancer staging of NPC (see Chapter 188, Nasopharyngeal carcinoma) is used by most.

TREATMENT

Undifferentiated NPC is a radiosensitive tumour and as such is usually treated with external beam radiotherapy. Such therapy is limited to the primary tumour and its regional metastatic spread. Chemotherapy is required in patients with disseminated systemic disease. There is now evidence that combined chemotherapy and radiotherapy provides better disease-free survival as compared with radiotherapy alone and combined chemoradiotherapy is therefore becoming routine practice in the UK.^{28,29}

Because of the tumour's close proximity to major structures, radiotherapy in this region is difficult to give and is associated with significant post-treatment morbidity. This includes mucositis, xerostomia, neck fibrosis and panhypopituitarism (see below under Long-term sequelae of treatment). Newer radiotherapy techniques, such as intensity-modulated radiation therapy (IMRT) may offer reduced morbidity following treatment as it becomes more readily available (see Chapter 200, Developments in radiotherapy for head and neck cancer). As craniofacial surgical techniques improve, surgical resection is now becoming appropriate in certain situations, particularly in primary recurrence following treatment.

Neuroblastoma

Neuroblastoma is a common malignancy of early childhood and is the most common malignancy in infants younger than one year. These tumours arise from undifferentiated sympathetic nervous system precursor cells of neural crest origin. The adrenal gland is the most common site of origin and additional sites include the sympathetic chain, posterior mediastinum and cervical regions. Neuroblastoma has a high propensity for lymphatic spread and regional lymph nodes are involved in up to 35 percent of cases. Metastases to the head and neck region are common, but primary neuroblastoma in the head and neck region is uncommon making up only 2–9 percent of the total.³⁰

PRESENTATION

Symptoms and signs will be dictated by the size and position of both the primary lesion and any metastases. Children with primary cervical neuroblastoma may present with a firm mass in the lateral neck, occasionally associated with a Horner's syndrome (due to cervical sympathetic chain involvement). Classical ophthalmological manifestations include proptosis and periorbital ecchymosis (usually secondary to intraorbital metastatic deposits). Bilateral eye haematomas are a classical sign (racoon eyes). Interestingly, chronic destruction of the ophthalmic sympathetic fibres in some children can lead to heterochromia of the irides. Involvement of the paranasal sinuses is also described.³⁰

ASSESSMENT

A full assessment of the disease will include obtaining a histological diagnosis by means appropriate to the location of the presenting lesions. Examination should include a visual assessment, intraoral inspection and a thorough neurological examination. MR and CT scanning are usually employed to assess the primary

Figure 98.3 Metastatic neuroblastoma from an adrenal primary is extending out of both sides of the lateral orbital walls (more marked on left – arrows). Patient has incidental scaphocephaly.

and the extent of any metastatic spread (**Figure 98.3**). An iodine-123-metaiodobenzylguanidine (MIBG) scan is a useful method of assessing metastases. A bone marrow aspirate and trephine should be performed, with a bone scan reserved for those with a negative MIBG scan. Urinary catecholamine levels should be measured (24 hour urine collection) as they are raised in over 90 percent of cases.

TREATMENT

The choice of single modality or multimodality therapy depends on the individual patient. Localized cervical neuroblastoma may be treated by curative surgery. Multi-agent chemotherapy is usually indicated in patients if resection is incomplete or where there is evidence of metastases. The role of radiation therapy is not well defined and is usually reserved for unresectable tumours.

PROGNOSIS

In young patients with resectable disease, complete excision offers the best chance of cure and at least a 90 percent survival rate. Primary neuroblastoma of the head and neck has a better prognosis than that of other sites. This is most likely due to the fact that it presents at an early stage. In disease in other sites the prognosis is poorer and it is worse in children over the age of one year at presentation.³⁰ [**/*]

Miscellaneous tumours

A large variety of tumours can rarely affect the head and neck region. The small numbers involved can make meaningful analysis of data difficult and it is not really feasible to address therapeutic questions in the context of randomized controlled trials. However, the UK Children's Cancer Study Group has formed a Rare Tumours Group which is developing guidelines for some of the rarer childhood cancers.

SOFT TISSUE SARCOMAS

A variety of sarcomas rarely affect the head and neck region in children and these are listed in **Table 98.2**. There is a bimodal age distribution with incidence peaking in the under fives and in adolescents. Those in the younger age group tend to have lesions situated in the head and neck region while older children present with lesions in the extremities. In general, these tumours have a tendency to recur locally and to metastasize. The treatment of choice is neoadjuvant chemotherapy followed by surgery and radiotherapy, as deemed appropriate (**Figure 98.4**). The prognosis remains relatively poor despite multimodality treatment.¹⁹

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma (SCC) outside the nasopharynx is extremely rare in childhood. There is some evidence of an association between SCC and previous exposure to immunosuppressive medication, and also previous irradiation for laryngeal papillomatosis. Pre-existing xeroderma pigmentosum makes any patient extremely susceptible to the development of cutaneous SCC. The principles of management of SCC in the head and neck in children are the same as in adults.

MALIGNANT TERATOMA

Malignant teratomas in the head and neck region are rare (most are benign) and usually present at birth, often as an airway emergency. Large tumours are usually diagnosed *in utero*, resulting in a multidisciplinary team being present at delivery to secure a safe airway. Tracheostomy may be necessary. Assessment should include nasendoscopy, alpha-fetoprotein and beta human chorionic gonadotrophin (hCG) levels, and imaging. Metastases are rare. Treatment is surgical excision although salvage chemotherapy and radiotherapy may be required. The prognosis is good in the absence of metastases.

Table 98.2 Soft tissue sarcomas of the head and neck region other than rhabdomyosarcoma.

Histological type	Site	Presentation	Treatment and prognosis
Fibrosarcoma	Peripheral nerves	Slowly enlarging painless mass	Metastatic disease is infrequent Complete resection is treatment of choice Prognosis generally good
Synovial sarcoma	Neck, larynx and oropharynx (see Figure 98.4) Foci of calcification are typical	Slowly enlarging mass often with compressive symptoms	Very rare in head and neck Multimodality treatment Five-year survival approximately 50%
Neurofibrosarcoma or malignant schwannoma	Peripheral nerves Develops in 3–16 percent of children with Von Recklinghausen neurofibromatosis (NF1)	Mass in neck +/- pain and weakness	Wide surgical excision and postoperative cranial nerve deficits common. Local recurrence and lung metastases common Poor prognosis if metastatic disease (especially in NF1)
Haemangiopericytoma	Arise from pericytes of Zimmerman (capillaries)	Nasal cavity and paranasal sinuses Nasal masses and epistaxis	Usually benign in infants but 20–35% malignant in older children Surgery +/- chemotherapy and XRT Overall survival 50–70%
Kaposi's sarcoma	Skin lesions +/- lymphadenopathy	Now mainly seen in children who are HIV positive	Surgery and XRT Prognosis poor
Ewing's sarcoma (extraskelatal)	In soft tissue adjacent to cervical spine	Neck mass Pain Spinal cord compression	Surgery +/- XRT and chemotherapy in similar fashion to rhabdomyosarcoma Prognosis poor

● Hedder Arnold / Scott-Brown 7E

CHORDOMA

This is a rare slow-growing bony tumour which is locally aggressive and which arises from embryonic remnants of the notochord. The presentation depends on the site of origin which, in the head and neck region, is most commonly found in the nasopharynx and adjacent skull base. Patients present with headache and diplopia and compression of the lower cranial nerves can result in a number of neurological signs (see Chapter 188, Nasopharyngeal carcinoma). Biopsy is necessary for diagnosis and MR and CT scanning will delineate the tumour extent. Complete surgical excision is rarely possible because of the anatomical location and adjacent structures and so postoperative radiotherapy is usually employed. The prognosis remains fairly poor.

LONG-TERM SEQUELAE OF TREATMENT

The aim of cancer treatment in children is to maximize the chance of long-term survival and at the same time minimize the side effects, particularly in the longer term. With overall five-year survival rates in children now in the order of 60–70 percent, it is particularly important to examine the effects of the more recently employed multimodality treatments. Children tolerate the acute side effects of radiotherapy and chemotherapy reasonably well but other sequelae may not become apparent for several years.³¹

Growth

Cranial radiotherapy can result in growth hormone deficiency and growth retardation and chemotherapy can also have significant effects on growth. Localized tumour treatments can also affect growth and function of specific organs or tumour sites. For example, radiotherapy

to the maxilla in a child can result in asymmetrical growth of the midface.

Reproductive function

An important issue for survivors of childhood cancer is the impact of the disease and its treatment on reproduction and the implications for the health of any offspring. In males there is evidence for impaired spermatogenesis after treatment but it appears that any sperm produced carries as much healthy DNA as produced by the population in general. However, it is not possible to predict fertility outcome in boys who receive treatment prior to puberty. Cryopreservation of sperm in young males (14–17 years) is effective but depends on the ability of the young patient to produce a specimen and, in the UK, consent for storage requires him to be ‘Gillick’ competent (see Chapter 63, The paediatric consultation). Radiotherapy to the hypothalamus or pituitary can result in precocious puberty in females and patients should therefore have their pubertal status checked regularly. Chemotherapy in general is less harmful to gonadal function in females but pelvic irradiation can affect ovarian function. Spontaneously conceived offspring of patients treated for cancer in childhood have no excess of congenital abnormalities or other diseases.³²

Cardiac problems

Anthracyclines have a significant cardiotoxic effect and can cause cardiac failure in later life. Long-term echocardiogram surveillance is recommended. Mediastinal radiotherapy can also result in impaired cardiac function (and an increased risk of breast carcinoma) and this should be monitored as appropriate.

Thyroid disorders

Thyroid dysfunction can result from radiotherapy to the neck or to the hypothalamic/pituitary axis. Chemotherapy is an independent risk factor. Survivors require regular thyroid function evaluation. Radiotherapy to the neck is a recognized aetiological factor in the development of thyroid carcinoma in later years.

Other otolaryngological manifestations of treatment

Radiotherapy to the head and neck region results in a large variety of long-term sequelae that can affect function and cosmesis. Damage to the major and minor salivary glands can cause xerostomia and subsequent tooth and gum disease. Post-radiotherapy scarring within

the nasopharynx can result in middle ear effusions and subsequent deafness, and in the region of the midface can result in recurrent sinusitis, temporomandibular joint dysfunction and trismus. Certain chemotherapeutic agents – notably cisplatin – are known to cause deafness and tinnitus. Immunodeficiency with a propensity to develop opportunistic infections of the head and neck may complicate some chemotherapy regimens.³¹

Cognitive and psychological problems

Surgery and/or radiotherapy to the brain or adjacent structures can result in neurocognitive defects such as low IQ, learning difficulties and an increased risk of seizures. Survivors of childhood cancer are at an increased risk for a wide range of disabling psychological problems such as low mood, low self-esteem and anxiety.

Follow-up

It is important to follow-up these children in the long term and to educate them and their parents about the possible late consequences of their treatment. It is also important to promote a healthy lifestyle and discourage cancer promoting behaviours such as smoking and excessive sun exposure.³²

THE DYING CHILD

The death of a child is one of the greatest tragedies that can befall a family. It is important to recognize that palliative care of the dying child should address not only the control of pain but the social, psychological and spiritual needs of children and their families. Planned terminal care for children has become increasingly community-based and therefore requires involvement of the primary health care team, including the patient's general practitioner at an early stage. An experienced and multiskilled team is required with a named key worker and access to advice and support 24 hours a day. The child should participate in the planning and provision of this care as much as is realistically possible.³³

To ensure optimum palliative care, the family and carers need to work with identical aims and a mutual acceptance of the inevitability of death. An appropriate person should discuss the fact that active curative treatment is no longer in the child's best interests and should start to negotiate a palliative care plan with the child and close family. Once the focus of treatment shifts from curative to palliative care, quality of life becomes of prime importance. Most children and their families will wish to maintain some semblance of normality while optimizing symptom control and minimizing medical intervention. For instance, many children will opt to remain at school for as long as they are

able, mixing with friends and getting a break from the home environment. Others may benefit from a daily visit at home from a play specialist.^{33,34}

Symptomatic control in the dying child has not been formally assessed and is often based on clinical experience and adapted from general paediatric practice and palliative care of adults. The World Health Organization's 'three stepladder' of analgesia can be applied in children with paracetamol, dihydrocodeine and morphine sulphate forming the standard steps. Laxatives and antiemetics may be required and appropriate sedatives may be required in the final stages of life.³⁴

Regular respite should be offered to parents and it is important to explore the financial assistance, benefits and grants that families may be entitled to. Practical help with funeral arrangements should be given and it is important to continue to support the grieving family after their child's death and to withdraw support slowly and appropriately.^{11,33,34}

KEY POINTS

- Head and neck tumours are uncommon in children.
- Early diagnosis is essential.
- Survival rates are improving.
- Multimodality treatment has improved the prognosis while reducing both early and long-term complications.
- Treatment should be provided by a specialized, centralized multidisciplinary paediatric oncology team.

Best clinical practice

- ✓ The vast majority of enlarged cervical lymph nodes in children are harmless. Imaging should usually be considered before biopsy. Excision biopsy may be appropriate for:
 - node > 2 cm;
 - supraclavicular area and/or fixed nodes;
 - weight loss and/or unexplained fever;
 - abnormal chest x-ray. [Grade C/D]
- ✓ FNA has a more limited role to play in the child than the adult. [Grade B]
- ✓ All children diagnosed with malignancy should be referred to a specialist centre. [Grade B]
- ✓ Children receiving chemotherapy should have central venous catheters placed for venous access and chemotherapy treatment. [Grade C/D]
- ✓ Disease-free survival is over 90 percent in many series of children with Hodgkin's lymphoma. [Grade B]

Deficiencies in current knowledge and areas for future research

- The long-term survival of children with cancer is improving, and a better appreciation of the long-term sequelae of treatment should result in an improved quality of life for children surviving cancer.
- We are likely to encounter more physical and psychological problems in adults related to cancer treatment in childhood.
- Basic science research should bring better understanding of the underlying aetiology of childhood cancer. This may help in introducing preventative measures such as vaccines and environmental interventions.
- Agreed protocols on the management of paediatric thyroid malignancy would be helpful.
- Centralization of services, the establishment of better databases and the implementation of multicentre trials will provide us with a better evidence base for the future management of childhood cancer.
- Better imaging techniques with wider access to sophisticated equipment will aid in more accurately assessing the initial disease and in detecting recurrence at an earlier stage.
- Greater knowledge of molecular genetics has resulted in new approaches to diagnosis and treatment. The advent of polymerase chain reaction (PCR) techniques has, for example, permitted the detection of cells bearing chromosomal translocations in the peripheral blood and bone marrow, thereby detecting minimal residual disease in lymphoma and even defining patients at high risk of relapse. Other novel strategies include the use of immunotherapy (immunotoxins or vaccines) to target specific cells or cell proteins.
- Radiotherapy techniques such as IMRT are allowing much greater flexibility in targeting tumours in awkward anatomical sites whilst avoiding some of the post-treatment complications. IMRT is an advanced mode of high precision radiotherapy where combinations of several intensity-modulated fields coming from different beam directions deliver a maximal dose to the tumour while minimizing the dose to surrounding tissues.
- Surgical advances, such as navigation systems with the use of endoscopes, mean that areas once inaccessible can now be approached surgically whilst maintaining good function and cosmesis.

In conclusion, we have made major advances in the investigation and management of childhood malignancy in the last 30 years and a number of promising diagnostic and treatment developments promise much in the next 30.

ACKNOWLEDGEMENTS

I wish to thank Dr Dermot Murphy, Consultant Paediatric Oncologist, Royal Hospital for Sick Children, Glasgow, for his comments on the manuscript and Dr Greg Irwin, Consultant Paediatric Radiologist, Royal Hospital for Sick Children, Glasgow, for providing the MR images.

SEARCH STRATEGY

The author has a personal bibliography which was supplemented by a Medline search using the key words branchial apparatus, child, congenital, thyroglossal duct, thyroglossal cyst, cystic hygroma and lymphangioma.

THE BRANCHIAL ARCHES

Embryology

The structures of the lateral face and neck are formed embryologically from the paired branchial arches, pouches and associated clefts (see Chapter 65, Head and neck embryology).

The branchial apparatus appears between the fourth and fifth weeks of foetal development. It consists of six paired branchial arches separated by branchial clefts externally and branchial pouches internally.

During normal development, the ventral parts of the first and second arches fuse to obliterate the ventral part of the first cleft. The remainder of the first cleft forms the cavum conchae and the external auditory meatus. The first branchial pouch forms the Eustachian tube and tympanic cavity. The fifth and sixth arches disappear early in foetal life. [****]

Terminology

Persistence of remnants of the branchial apparatus gives rise to a number of well-recognized congenital anomalies in the head and neck. A persistent cleft will give rise to an external sinus, a blind ending opening onto the skin. A persistent pouch will cause an internal sinus typically opening into the pharynx whereas persistence of both cleft and pouch will cause a fistula with an internal and external (or upper and lower) opening.

Anomalies that cause a single opening or sinus or the persistence of a tissue remnant are more common than fistulae and include pre-auricular sinuses, cysts and skin tags.

FIRST BRANCHIAL ARCH (CERVICO-AURAL) FISTULA

This is rare and accounts for less than 5 percent of branchial cleft anomalies. The external fistulous opening

in the neck varies in position but lies on a line from the tragus to the hyoid bone. The opening is often fairly inconspicuous and may look like a small skin-lined pit. The upper end of the fistula is also variable. There may be an opening anterior to the tragus; the track of the fistula may run under the floor of the external auditory canal and occasionally opens at the osseo-cartilaginous junction in the external auditory meatus.

In some cases, a skin-covered band runs from the floor of the meatus to the umbo. If seen, it makes the diagnosis certain.

Histology

The cervico-aural fistula is usually a sizeable track lined with squamous epithelium. Work¹ has divided them into two types according to the presence or absence of mesothelial elements within the wall.

Type 1 lesions are of ectodermal origin and are present medial to the concha. Type 2 lesions are both ectodermal and mesodermal in origin and contain mesodermal structures such as cartilage and hair follicles (Figure 99.1). [***]

The lower opening of the type 2 fistula is usually below the angle of the mandible.

Presentation

The opening at either end of the track is present at birth and may become more obvious by the discharge of epithelial or sebaceous debris (Figure 99.2).

The fistula may become acutely infected and may rarely progress to abscess formation. Being lined with skin, cervico-aural fistulae do not discharge mucus.

Figure 99.1 Histology of a first arch cervico-aural fistula.

Investigation

If there is doubt about the nature of the fistula, a radio-opaque sinogram using water-soluble contrast will demonstrate the extent of the track and confirm the position of the upper end (Figure 99.3). MR scanning may show the track but will not demonstrate its relationship to the facial nerve.

Treatment

Because the fistulous track is lined with squamous epithelium, it will contain desquamated material, which may become infected. Surgical excision of these lesions is usually advocated. Surgery is easier before either acute infection or abscess has supervened. [**/*]

Surgical excision necessitates the dissection of the track in its entirety. [*]

© Hodder Arnold / Scott-Brown 7E

Figure 99.2 The external opening of a cervico-aural fistula.

Figure 99.3 Sinogram showing the course of a cervico-aural fistula.

A parotidectomy type incision is modified to include the lower opening of the fistula. The fistula at this point can be followed for a small distance upwards and when its nature and direction are confirmed, the facial nerve trunk must be identified as it leaves the skull base and enters the parotid gland. The mandibular branch in particular should be followed so that it can be preserved while freeing the fistulous track. Sharp dissection will often be required to free the nerve from the track.

In most instances the fistula will run deep to the branches of the facial nerve, which may be adherent if there has been recurrent infection, though the relationship is unpredictable (Figure 99.4).

The upper part of the first arch fistula also has an unpredictable relationship to the cartilages of the external auditory canal (EAC). It may terminate at the canal or may form a duplicated canal parallel and inferior to the EAC proper.

The fistula does not extend medial to the cartilaginous canal but a strand may cross the lumen of the canal from the osseous-cartilaginous junction to be attached to the umbo.

Facial nerve exposure and protection is required in nearly every case of first branchial cleft fistula. If this is done, then the risk to the facial nerve is minimized.

Peroperative facial nerve monitoring is advisable. [*] The very superficial position of the facial nerve in small children must be considered when making the approach to the nerve.

The upper end of the fistula must be followed and excised to ensure that no squamous epithelium remains, and this may require opening of the external auditory canal. Closure of the wound with suction drainage and, if necessary, packing of the ear canal completes the operation.

SECOND BRANCHIAL ARCH FISTULA

Second arch fistulae and sinuses are much the commonest of the branchial arch anomalies (95 percent). The second

branchial arch forms the epidermis of the upper neck and dorsal pinna. The mesoderm forms the facial muscles and the body of the hyoid, and the endodermal elements form the root of the tongue, the foramen caecum, the thyroid stalk and the tonsil. Malfusion of these structures may lead to the formation of the second arch branchial fistula. Second branchial arch fistula may form part of branchio-oto-renal syndrome.^{2,3}

Presentation

The second branchial arch fistula presents as a congenital opening on the lower neck, anterior to the sternomastoid muscle. The track of the second arch fistula is directed upwards and medially to pass between the internal and external carotid arteries. The upper end communicates with the pharynx through the tonsil (Figure 99.5). These fistulae nearly always leak clear or mucoid fluid from the lower opening and may become infected. On occasion, the infected track may form an abscess requiring surgical drainage.

Investigation

As a rule, the diagnosis is evident and no further investigation is required. If there is doubt, a contrast sinogram can be performed to define the track.

Treatment

Because of the risk of infection, excision of second arch branchial fistulae is advisable. Surgery can be performed at any age and aims to excise the track completely. An elliptical incision is made around the external opening and the track can be followed upwards. If the distance between the lower end and the pharynx is too great to

Figure 99.5 A branchial fistula removed in continuity with the tonsil.

allow good access, a second skin crease incision is made further up the neck to enable the upper part of the track to be visualized and excised. The track will be seen to enter the pharyngeal muscle at the level of the tonsil and can be ligated and excised at this level. Sometimes the track can be followed into the tonsil, which can be removed intraorally in continuity (Figure 99.6).

Care must be taken to identify the lingual nerve in the upper part of the dissection. Complete excision of the fistula should prevent any recurrence.

THIRD AND FOURTH BRANCHIAL ARCH ABNORMALITIES

The third and fourth branchial arches form part of the hyoid bone and the muscles of the larynx and pharynx. The pouches also form the thymus gland, the parathyroids and part of the thyroid. Agenesis gives rise to the 'DiGeorge' anomaly. This is characterized by partial or complete aplasia of the thyroid and parathyroid glands, often with associated craniofacial and cardiac anomalies. Sinuses and fistulae of these arches are rare.

Presentation is usually as an abscess in the neck, most commonly on the left, communicating with the apex of

Figure 99.6 A case of branchio-oto-renal syndrome, showing the external opening of a second arch branchial fistula and deformity of the outer ear.

the piriform fossa (Figure 99.7). The appearance may be that of an acute suppurative thyroiditis. Typically, there is diagnostic delay and the child may have had several surgical interventions. Treatment requires endoscopy of the piriform fossa and complete excision of the track and the inflammatory mass.^{4,5} [*]

Pre-auricular sinus

EMBRYOLOGY

The outer ear is formed from cartilaginous tubercles of first arch origin which fuse to form the pinna. A blind-ended sinus results from incomplete fusion and the inclusion of epithelial tissue forms a skin lining to the sinus. There may be a family history of such anomaly. The branchio-oto-renal syndrome is determined by an autosomal dominant gene and includes external ear abnormality, pre-auricular sinus and renal disorder.^{2,3}

PRESENTATION

The opening of the sinus is apparent at birth and is often bilateral. There may be some sebaceous discharge from the punctum. As a rule, these lesions give little trouble and can be safely left alone. In some patients there is recurrent episodic infection which may progress to abscess formation. Because the sinus is lined with squamous epithelium, spontaneous resolution does not take place.

TREATMENT

If the sinus is free of infection, it can be left alone, but many of the cases will be subject to repeated episodes of

Figure 99.7 Sinus opening at apex of left piriform fossa in a case of fourth branchial arch sinus. The patient had presented with recurrent neck abscesses.

infection and should be excised. An ellipse of skin around the punctum is marked out and the track followed carefully. It can be helpful to instil some methylene blue dye into the track to make it more visible during the dissection. The aim of the operation is to remove all vestiges of squamous epithelium, so the track must be dissected out meticulously and in one piece.

DISORDERS OF THE THYROGLOSSAL DUCT

Considered under this heading are:

- thyroglossal duct cyst;
- thyroglossal duct fistula;
- lingual thyroid.

Embryology

The thyroid primordium develops in the floor of the primitive pharynx at the site of the foramen caecum, which lies in the midline at the junction of the posterior one-third and anterior two-thirds of the tongue. The descending thyroid gland migrates through the tongue tissue, passing anterior to the hyoid bone to lie in the anterior neck. The line of descent from the foramen caecum is marked by the thyroglossal duct. If involution of the duct is incomplete, a cyst may develop at any point along the track.

Presentation

Surprisingly for a congenital lesion, presentation of a thyroglossal cyst is often delayed well beyond infancy and into early childhood. The cyst is usually midline but in 10 percent of cases may present laterally, usually on the left.⁶ Protrusion of the tongue, by elevating the hyoid bone, results in the cyst (or fistulous opening) being pulled upwards (Figures 99.8 and 99.9).

Figure 99.8 A thyroglossal duct fistula.

Investigation

If there is doubt about the diagnosis, ultrasound examination will clarify the nature and position of the cyst. Aspiration is unnecessary and may lead to infection and fistula formation. [*]

The thyroglossal duct cyst, while derived from the descending thyroglossal track, does not contain the only functioning thyroid gland tissue. It may contain thyroid tissue in the wall, but unless there is a lingual thyroid, the thyroid gland will be in the normal position. It is not necessary to do isotope thyroid scans or thyroid function tests before surgery for thyroglossal cyst.

Treatment

Treatment of thyroglossal duct cyst is by excision. The optimum operation is as described by Sistrunk.⁷ [**]

A horizontal skin crease incision is made over the convexity of the cyst. If there is a fistula, an ellipse of skin is taken to include the opening. The cyst or track is then dissected out and the middle segment of the hyoid exposed and skeletonized. The thyroglossal duct goes through or deep to the body of the hyoid bone, so the body is excised in continuity. The track is then followed through the tongue in the midline. If no track is visible, a core of tissue is removed up to the foramen caecum.

Removal of a thyroglossal cyst results in a recognized recurrence rate of between 4 and 10 percent. [**] Revision surgery is more unpredictable and requires an en bloc removal of inflamed tissue.

Thyroid tissue has been observed histologically in 46 percent of cases of excised thyroglossal duct cysts.⁸

LINGUAL THYROID

If the thyroid primordium fails to descend into the neck, thyroid tissue will remain at the foramen caecum. There may therefore be no thyroid tissue at the usual pretracheal

© Hodder Arnold / Scott-Brown 7E

Figure 99.9 A thyroglossal duct fistula with the tongue protruded, showing the pull on the fistulous track.

site and all the thyroid gland is represented by that at the foramen caecum.⁹

Presentation

Lingual thyroid is extremely rare. In a review of thyroid abnormality in 29,000 autopsies, only four lingual thyroids were identified.¹⁰ [****] It usually presents as a mass on the base of the tongue in infancy or childhood, leading to dysphagia or airway compromise (Figure 99.10). It may be found coincidentally on isotope scanning in the investigation of hypothyroidism. Rarely, a lingual thyroid may present acutely as a result of bleeding into the ectopic thyroid tissue.

Investigation

- MR or CT scanning will demonstrate the lesion in the sagittal or coronal plane (Figure 99.11).
- Radioactive iodine scanning with I¹²³ or I¹³¹ will demonstrate active thyroid tissue.
- Thyroid function tests will usually demonstrate the presence of hypothyroidism.

© Hodder Arnold / Scott-Brown 7E

Figure 99.10 A lingual thyroid.

Figure 99.11 CT scan showing the lingual thyroid.

Treatment

If the lingual thyroid is small and causing no symptoms, suppression of thyroid stimulating hormone (TSH) with oral thyroxine may result in reduction in size. [**] The advice of an endocrinologist, particularly in children, is essential. If the lesion is larger and causing dysphagia or airway obstruction, surgical excision is required. Since thyroid replacement therapy is in most cases necessary in any case, there need be no concern at removing all extant thyroid tissue. There is no hazard to the parathyroid glands, which are embryologically from a different origin and will not be within the lingual thyroid tissue.

Peroral access to the lingual thyroid is usually possible, with midline splitting of the dorsal tongue to gain access to the substance of the lingual thyroid. If the ectopic tissue is more deeply buried, a suprahyoid external approach may be necessary. Postoperatively, surveillance of thyroid function is essential. [**]

LYMPHANGIOMA

Embryology

Lymphangioma (LA) refers to a group of developmental anomalies in which the lymphatics fail to connect in the normal way to the venous channels. As a result, there are large fluid-filled spaces occupying the tissues and expanding tissue planes. Histologically, these lesions consist of widely dilated lymphatic spaces with walls of varying thickness. The lesions may be macrocystic or microcystic. The macrocystic lesions are often large and compressible, though frequently multilocular, whereas the microcystic type is often smaller and firmer. The macrocystic lesion, with its well-defined margin, is commonly referred to as 'cystic hygroma.' Because the failure of proper development of the venous lymphatic relationship manifests most frequently in the developing paired jugular lymph sac systems, cystic hygroma is most common in the face, neck and mediastinum.

Presentation

The hygroma is usually evident at birth as a smooth, soft swelling, which may be fluctuant. Being filled with fluid, it can often be transilluminated. The hygroma may be enormous and cause immediate and fatal airway obstruction. It can be diagnosed antenatally by ultrasoundography; steps to secure the airway can then be planned prior to delivery. The swelling may enlarge during childhood, sometimes triggered by intercurrent upper respiratory infections (Figure 99.12). This may lead in turn to acute infection within the hygroma, which can become tense and hard. If this happens to the

© Hodder Arnold / Scott-Brown 7E

intraoral or intralingual part, severe airway obstruction will result. If the lesion is extensive in the head and neck, there may be intraoral lesions forming small clear cysts in the mucosa. These are sometimes vascular and may bleed spontaneously but can be removed easily with laser or diathermy.

Natural history

Cystic hygromas of the head and neck do not involute spontaneously. Some progression may take place with enlargement, and infiltrative growth into previously unaffected areas sometimes happens. Recurrent episodes of acute infection may arise and the lesion will become larger, painful and inflamed. As a result of this infection, related lymph nodes can become enlarged. The activity in cystic hygroma may subside with increasing age. There is no potential for malignant change. Rarely, sequestration of fluid within a cystic hygroma, especially in neonates, may result in hypovolaemic shock and widespread intra-vascular thrombosis.

Investigation

Although as a rule the diagnosis is apparent and no particular investigations are needed, ultrasonography will reveal the cystic nature of the lesion and its relationship to the surrounding tissues. It will also distinguish between macro- and microcystic disease. Cross-sectional imaging will be required if surgery is contemplated. [*] MR scanning is preferable as it provides better soft tissue delineation and avoids exposure to ionizing radiation.¹¹ It will normally need to be carried out under general anaesthesia. There is little or no value in fine-needle aspiration for cytology unless underlying neoplasia is suspected.

© Hodder Arnold / Scott-Brown 7E

Figure 99.13 Histology of cystic hygroma infiltrating the parotid tissue.

Treatment

If the cystic hygroma is small and is cosmetically and functionally acceptable, no treatment other than observation will be required. [**]

Sclerotherapy

Macrocytic disease is amenable to aspiration and the instillation of sclerosant. Most experience is with OK 432, although other agents such as alcohol, bleomycin, ethanolamine oleate and trichloroacetic acid have been used.¹² OK 432 is a lyophilized incubation material derived from group A pyogenic streptococcal culture, which induces an intense inflammatory reaction within the hygroma and obliteration of the cystic space. In a multicentre trial of OK 432,¹³ a group of patients received four doses of the material at six to eight week intervals. There was a successful outcome in 86 percent of the cases, predominantly for macrocystic disease. [**/*]

Surgery

Microcystic disease or macrocystic disease not amenable to sclerotherapy presents a formidable challenge (Figure 99.13). It will usually require surgical resection and complete extirpation may be impossible. A long-term review from Copenhagen indicated that 50 percent of such patients had residual disease, 44 percent had impairment of speech, swallowing or breathing and 36 percent had cosmetic deformity that caused them concern.¹⁴ [**/*]

Surgery requires great attention to anatomical structures, which are enveloped in the hygroma tissue. Residual or recurrent hygroma is more likely in supra-hyoid disease because of the more complex anatomy. Neurovascular structures should not be damaged in an

attempt to remove every last remnant, since this will have long-term adverse consequences for the patient.¹⁵

KEY POINTS

- A knowledge and understanding of the embryology and often complex anatomy of congenital anomalies of the head and neck is essential before treating these disorders.
- Investigation is not always required but careful imaging in consultation with a paediatric radiologist may be helpful in planning treatment.
- The term 'cystic hygroma', though commonly used, refers to a group of disorders which are better considered as 'lymphangiomas'.

Best clinical practice

- ✓ In first arch (cervico-aural) fistula, surgical excision necessitates the dissection of the track in its entirety. Facial nerve exposure and protection is required in almost every case. [Grade D]
- ✓ Because of the risk of infection, excision of second arch branchial fistulae is advisable. [Grade D]
- ✓ Simple excision of a thyroglossal duct cyst is inadequate. The body of the hyoid must be excised and the track followed to the foramen caecum. [Grade C]
- ✓ Suppression of TSH with oral thyroxine may result in regression of a lingual thyroid. [Grade C]
- ✓ In lymphangioma surgery, neurovascular structures should not be damaged in an attempt to remove every last remnant. [Grade D]

Deficiencies in current knowledge and areas for future research

- Thyroglossal duct abnormalities are increasingly dealt with by otolaryngologists with training and expertise in head and neck surgery; recurrence due to inadequate primary surgery should become less common.
- Continuing improvements in medical imaging should help treatment planning for complex head and neck abnormalities.
- The results of continuing studies on sclerotherapy for lymphangioma will help define the place of this method of treatment of these challenging disorders.

SEARCH STRATEGY

Systematic reviews were identified first using the key words: reflux (gastric, gastro-oesophageal, gastropharyngeal, gastronasopharyngeal, gastrolaryngopharyngeal); and subject headings in the Cochrane Database of Systematic Reviews, the Database of Abstracts of Reviews of Effectiveness, and the ACP Journal Club. Individual articles were then identified using the same search terms in Ovid Medline. Articles were also identified from bibliographies and from the author's own collection.

GASTRO-OESOPHAGEAL REFLUX

Definitions

Gastro-oesophageal reflux is the retrograde passage of stomach contents into the oesophagus. The refluxate need not be acidic, and is often neutral or even alkaline. Some degree of reflux is extremely common in neonates and usually has few, if any, symptoms: this is termed physiologic reflux. Pathologic reflux, on the other hand, is synonymous with gastro-oesophageal reflux disease and implies that the child is coming to harm in some way. This may be in the form of symptoms, or as tissue damage in the absence of symptoms (silent reflux). Secondary reflux occurs in a child predisposed by the presence of other abnormalities of the oesophagus, such as tracheo-oesophageal fistula or neuromuscular disease. Gastro-pharyngeal reflux ascends above the level of the upper oesophageal sphincter and has been implicated in a number of respiratory and otolaryngological diseases.

Natural history

Physiologic reflux is almost universal in neonates. These reflux episodes are usually postprandial, brief and asymptomatic. One study showed healthy preterm infants with no symptoms or signs of reflux having between 40 and 145 (median 72) reflux events per 24 hour period, and these were more common immediately after feeds.¹ Reflux becomes less frequent at certain predictable developmental milestones, such as sitting and weaning onto solids. At the age of four months, 67 percent of infants have at least one episode of regurgitation per day as reported by their parents: by the age of seven months this figure has fallen to 21 percent, and at a year regurgitation will only be present in 5 percent.² Heartburn and regurgitation are reported by around 2 percent of three to nine year olds and 5–8 percent of 10–17 year olds, although few seek or receive treatment.³ It is likely that a significant proportion of these children will go on to have gastro-oesophageal reflux as adults.^{4,5}

Pathophysiology

The short length of the intra-abdominal portion of the oesophagus in neonates may predispose them to reflux to some degree, but anatomical factors are not thought to be a major factor in paediatric reflux. Hiatus hernia in particular is only present in a small minority of children with reflux.⁶ Nor is there evidence of an abnormality of resting muscle tone in the lower oesophageal sphincter. The evidence suggests that reflux in children of all ages is primarily caused by transient lower oesophageal sphincter relaxations.^{7, 8, 9, 10} The lower oesophageal sphincter is not a defined ring of muscle, but rather a physiological barrier consisting of an area of increased muscle tone in the lower oesophagus. Transient relaxations can occur for many reasons, including gastric distension, and are prolonged (more than ten seconds) compared with the normal relaxation that occurs during swallowing.¹¹

Children with neuromuscular disorders may have upper gastrointestinal dysmotility with gastroparesis and retroperistalsis.

Reflux is more likely in the presence of a nasogastric tube.¹ It is also more likely in infants fed formula milk rather than breast milk, as the former passes from the stomach into the duodenum more slowly.¹² Intolerance to cow's milk may also play a role for some infants with reflux.¹³

A recent study has suggested the possibility of a gene on chromosome 13q14 predisposing infants to severe reflux,¹⁴ although further studies with more rigorous case definition are required to confirm this.

Symptoms and signs

The most common manifestation of reflux is regurgitation of feeds, also known as possetting. Mild, infrequent regurgitation is common and is not usually regarded as a reason to intervene medically. More affected infants may show evidence of colicky pains and irritability, perhaps with arching of the back. With severe reflux (and now clearly in the realms of gastro-oesophageal reflux disease) infants may have severe vomiting, aversion to feeds and failure to thrive. Abnormal posturing of the head and neck (Sandifer syndrome) is an uncommon presentation of reflux disease.

Otolaryngological manifestations

APNOEAS AND APPARENT LIFE-THREATENING EVENTS

Apnoeas are not uncommon in infants, particularly those born prematurely. Gastro-oesophageal reflux causing laryngospasm may be a factor in some, but other causes need to be considered, including tracheomalacia, seizures

and central apnoea.¹⁵ Reflux events are common in neonates and are not always associated temporally with apnoeas,¹⁶ but if symptoms, signs and investigations suggest that reflux may be a factor, anti-reflux treatment may be effective.¹⁷ [**]

Apparent life-threatening events (ALTEs) occur when a child becomes limp, bradycardic, cyanosed and clearly requires resuscitation. Infants with ALTEs are at risk of sudden infant death syndrome (SIDS). Approximately half of ALTEs are thought to be related to reflux-related laryngospasm or aspiration.^{18, 19} Structural airway anomalies are also common, but central apnoeas and nonaccidental injury should be considered in the differential diagnosis.

AIRWAY DISORDERS

Gastro-oesophageal reflux may cause a variety of upper airway symptoms in children and has been found to be associated with hoarseness,²⁰ recurrent croup^{21, 22} and 'laryngitis'.²³ Controlled studies of the effect of anti-reflux treatment on these symptoms are lacking.

Gastro-oesophageal reflux is extremely common in children with laryngomalacia,^{24, 25, 26, 27} but it is difficult to separate cause from effect. The highly negative intrathoracic pressures generated by a child with upper airway obstruction will encourage reflux of gastric contents. Reflux may, in turn, worsen airway obstruction by causing laryngeal oedema and laryngospasm. Treatment of the laryngomalacia by aryepiglottoplasty produces significant improvement in reflux on pH testing.²⁸ Equally, anti-reflux treatment can be very useful in improving the stridor of laryngomalacia, and may obviate the need for surgery in a proportion of those most affected. [*]

Gastro-oesophageal reflux is common in children with subglottic stenosis and has been postulated as a contributory factor in the development of the stenosis.^{29, 30} As with laryngomalacia, however, it is difficult to know whether the reflux is a cause or an effect of the airway obstruction. Many surgeons feel that reflux is potentially very deleterious at the time of reconstructive surgery³¹ and prophylactic anti-reflux therapy is often prescribed,³² although evidence that this makes a difference is lacking.³³ [*]

Laryngeal and laryngo-tracheo-oesophageal clefts are associated with oesophageal dysmotility problems, and reflux is almost universal. Most surgeons would advocate anti-reflux treatment for these children, particularly around the time of cleft repair, either with medication³⁴ or fundoplication.³⁵ [*]

Although it has been suggested that reflux may exacerbate the clinical course of children with recurrent respiratory papillomatosis^{36, 37} and choanal atresia,³⁸ supporting evidence is lacking. Few surgeons use anti-reflux medications routinely in these situations at present.

RHINOSINUSITIS

The reflux of stomach contents into the nasopharynx or even the nose has been postulated to cause inflammation and oedema, and thereby lead to chronic rhinosinusitis. Reflux might also cause nasal disease through colonization of the nose with *Helicobacter pylori* and autonomic dysfunction.³⁹ Evidence in support of such an association in children is limited. A diagnosis of sinusitis and a history of sinus surgery are both more common in children with a diagnosis of gastro-oesophageal reflux than in children without reflux.²³ Previously diagnosed reflux is also common in children with chronic rhinosinusitis, and this has been demonstrated in uncontrolled studies, both prospective⁴⁰ and retrospective.⁴¹ In most children this reflux is gastro-oesophageal, but a substantial minority have demonstrable reflux into the nasopharynx.⁴⁰ A single small controlled study has shown gastro-nasopharyngeal reflux on pH testing to be more common in children with chronic rhinitis than controls.⁴² Children undergoing adenoidectomy have been reported as having gastro-oesophageal reflux more often than children undergoing ventilation tube insertion, but the diagnostic criteria for reflux were variable and not standardized.⁴³

Anti-reflux medication has been reported to produce a marked improvement in sinus symptoms in studies with small numbers of highly selected children with sinus disease and proven reflux.^{40, 41, 44} Two children with refractory sinusitis and otitis media associated with reflux have been reported as having complete resolution of their symptoms after fundoplication.⁴⁵

The case for an association between reflux and rhinosinusitis is intriguing but remains unproven. Controlled studies with adequate numbers are required to establish the nature of any association and the response to anti-reflux treatment.

OTITIS MEDIA

A recent study by Tasker and co-workers⁴⁶ showed extremely high levels of pepsin in middle ear effusions from children with otitis media (OME). The pepsin was not produced in the middle ear and was present in far higher concentrations than could be found in blood, so it could only have got there from gastric reflux. Gastric acid and pepsin could cause inflammation of middle ear mucosa and dysfunction of the Eustachian tube, and reflux is therefore a plausible cause of OME. However, supporting evidence for such an association is lacking. Although small studies have shown reflux on pH testing in more than half of children with OME or recurrent acute otitis media,^{47, 48} a large case-control study (9900 children) showed otitis media to be marginally less common in children with reflux than controls.²³

It has been suggested that reflux may cause referred otalgia which, in a fretful child, may lead to an erroneous diagnosis of acute otitis media.⁴⁹ This is an interesting suggestion that merits further study.

Diagnostic tests

In clinical practice, probably the most common 'diagnostic' intervention for a child with suspected reflux is an empirical therapeutic trial of anti-reflux treatment. This reflects the fact that the available investigations, such as pH testing, are far from ideal. Diagnostic testing remains essential, however, when a child fails to respond to treatment, has atypical symptoms or is being considered for anti-reflux surgery. It is likely that, over the next few years, intraluminal impedance will prove to be the investigation of choice. Children with suspected intolerance of cow's milk should be referred to a paediatric gastroenterologist for further investigation.

Radiological contrast swallow studies are reasonably sensitive but not specific – if they show reflux, it is likely to be genuine, but a normal study certainly does not exclude significant reflux. The main value of a contrast study is in excluding rare anatomical anomalies such as malrotation, pyloric stenosis, hiatus hernia, strictures and webs.⁵⁰ [***]

Radionuclide scintigraphy (performed after the oral ingestion of technetium-labelled milk) has some advantages over pH monitoring in being able to show delayed gastric emptying, aspiration and nonacid reflux events.⁵⁰ Like the contrast study, however, it lacks sensitivity and gives only a brief time for measurement, and is therefore not routinely used in clinical practice. [***]

Currently, the 'gold standard' investigation for gastro-oesophageal reflux is 24-hour ambulatory pH probe monitoring. The probe is passed transnasally into the distal oesophagus. Measurements are taken every few seconds and calculations are made of the frequency and duration of oesophageal acid exposure. The results are reasonably reproducible, and are especially valuable if reflux events can be temporally related to symptoms (**Figure 100.1** and **Table 100.1**). Some degree of reflux is found in normal children at all ages, but is more common in infants. The results must be interpreted, therefore, with reference to the child's age. The reflux index is the percentage of time spent with a pH less than 4: studies of normal children have suggested an upper limit of normal of 12 percent in the first year of life and 6 percent thereafter.⁵⁰ [***]

The correlation between otolaryngological symptoms and the presence of gastro-oesophageal reflux on conventional pH monitoring is, unfortunately, poor. The correlation is improved when dual-probe pH monitoring is performed, using a probe in the pharynx as well as one in the lower oesophagus.^{51, 52, 53, 54} The upper probe is placed above the cricopharyngeus

pH Channel

Compressed 24-hour pH Graph

**Figure 100.1** A typical pH study result showing severe reflux.**Table 100.1** Period table.

Item	Total	Upright	Supine	Meal	PostP	None
Duration of period (HH:MM)	24:00	15:06	08:54	3:01	04:36	00:04
Number of acid refluxes (#)	152	120	32	52	42	0
Number of long acid refluxes (#)	15	13	2	4	8	0
Longest acid reflux (min)	47	33	47	33	21	0
Total time pH below 4.00 (min)	374	296	77	107	127	0
Fraction time pH below 4.00 (%)	26.0	32.7	14.5	58.9	46.0	0.0

posterior to the larynx, ideally at a similar level to the vocal cords. An x-ray can be used to confirm position. The lack of control data make it difficult to establish what level of gastro-pharyngeal reflux, if any, can be considered normal, but a reflux index of 2 percent in infants and 1 percent in children has been used by some.⁵⁴ [***]

Unfortunately, pH probe results do not always seem to correlate with symptoms in clinical practice. It must be borne in mind that milk is alkaline and an infant's stomach contents are likely to be of neutral pH (or only weakly acidic) for approximately two hours after each milk feed. Reflux events with a pH of greater than 4 will not be recorded by the pH probe. For neonates fed continuously or every one or two hours, this makes pH monitoring effectively useless. These events may still be injurious by causing laryngospasm or aspiration, for example. In addition, pepsin is active up to a pH of 6, and it may be pepsin rather than acid that causes the majority of tissue injury. Brief reflux events (less than 15 seconds) are also not recorded.

Intraluminal impedance testing uses a probe with a series of electrodes along its length. It is passed into the oesophageal lumen in the same way as a pH probe. When

a bolus (solid or liquid) passes by, the electrical resistance between adjacent electrodes drops and the bolus can therefore be detected. Furthermore, the direction of travel of the bolus allows swallows to be distinguished from reflux events, and the height of a reflux event can also be detected. A pH probe at the distal end of the device completes the picture. With this technique it has been possible to show that 73 percent of reflux events in infants occur postprandially and are of neutral pH.⁵⁵ In most of these events, the refluxate reaches the pharynx. Equipment suitable for ambulatory use has recently been developed, but normal values for children have yet to be established. [**]

The findings on endoscopy can be highly suggestive of reflux, particularly the presence of hypopharyngeal cobblestone mucosa, oedema of the arytenoids, obliteration of the ventricle, vocal fold oedema and oedema of the posterior commissure (**Figure 100.2**). Other suggestive features include lingual tonsil hypertrophy, blunting of the carina and increased bronchial secretions. Some studies have shown a strong correlation between these findings and a diagnosis of gastro-oesophageal reflux,^{56, 57} while others have not.⁵³ Oesophagitis is diagnostic, but is

Figure 100.2 Endoscopic view of the larynx in a one-year-old girl with Down syndrome and a repaired tracheo-oesophageal fistula. There is severe cobblestoning of the mucosa on the laryngeal surface of the epiglottis, and also a subglottic stenosis, both attributed to reflux.

present in only a minority of children with reflux. In fact, the appearance of the oesophageal mucosa is often normal despite the presence of reflux, and biopsy is required to establish the diagnosis with certainty. [***]

Treatment

For many children with physiological reflux or very mild symptoms, expectant treatment is reasonable. If more significant reflux is suspected, a therapeutic trial of feed thickeners and advice on positioning, possibly with concomitant acid suppression, should be the first step.

There have been a number of randomized controlled trials that support the effectiveness of feed thickeners in reducing regurgitation, although none met the quality criteria for inclusion in a recent Cochrane systematic review.⁵⁸ Feed thickeners have the advantage of increasing the caloric value of the milk and thus promoting weight gain, but a modified teat may be required to allow the infant to feed effectively. [****]

The ideal position to reduce reflux in children over a year old is the left lateral position with the head of the bed elevated.⁵⁰ In infants, the prone position is best for reducing reflux, but has also been shown to increase the risk of SIDS. It is therefore not recommended. The left lateral position may be just as good as prone⁵⁹ if it can be maintained safely, but the right lateral position makes reflux worse.⁶⁰ Head elevation shows no benefit in infants and the use of an infant seat to achieve a semi-erect position actually makes reflux worse.⁶¹ [****]

Antacids run the risk of causing toxicity in infants due to their high aluminium content and prolonged treatment is not recommended.⁵⁰ Alginates (such as Gaviscon) are widely used in children but there is no published

paediatric evidence to support their use. Prokinetic agents were once popular but the only consistently effective agent, cisapride, has been withdrawn due to cardiac side effects. Domperidone has its advocates, particularly for use in children with neurological disorders.

Acid suppression therapy is the mainstay of treatment for children with significant symptoms of gastro-oesophageal reflux disease. There are no trials, however, to demonstrate the effectiveness of such treatment for extra-oesophageal symptoms of reflux in children. Placebo-controlled trials support the use of H₂ receptor antagonists for children with oesophagitis.^{62, 63} Numerous trials have shown proton pump inhibitors (PPIs) to be more effective than H₂ antagonists in adults, but studies of PPIs in children are limited to case series. It is difficult, therefore, to make clear recommendations about which drug to choose except to say that H₂ antagonists are widely used and seem to be effective, while PPIs may be more effective but the evidence to support their use in children is lacking. Data on the effects of long-term acid suppression in children are also lacking. [**]

Selected children with reflux resistant to medical therapy may be selected for surgery in the form of a fundoplication. The procedure (now often performed laparoscopically) involves wrapping the fundus of the stomach around the intraabdominal portion of the oesophagus to produce a valve-like effect. Case series suggest that the procedure can be extremely effective for selected children with extra-oesophageal symptoms.^{45, 64} [**]

KEY POINTS

- A degree of reflux is physiological in neonates.
- The prevalence of symptomatic reflux declines with age after the neonatal period.
- Some relationship between reflux and airway disorders has been established.
- A relationship between reflux and disorders of the ear and nose has been postulated but remains unproven.

Best clinical practice

- ✓ Reflux is often physiological and can be managed expectantly if symptoms are mild. [Grade C]
- ✓ A therapeutic trial of positioning, feed thickeners and acid suppression is an appropriate first step when significant reflux is suspected. [Grade C]
- ✓ The left lateral position is effective and in children above one year old a degree of head elevation should also be used. [Grade C]

- ✓ Acid suppression with H₂ receptor antagonists or PPIs appears to be safe and effective but supportive published evidence is lacking. [Grade C]
- ✓ Diagnostic tests have limitations and should be reserved for cases where medical treatments have failed. [Grade C]
- ✓ Fundoplication surgery should be considered where symptoms are significant and medical treatments have failed. [Grade C]

Deficiencies in current knowledge and areas for future research

The relationship between reflux and otolaryngological disorders has been difficult to establish. In part, this may reflect the limitations of the currently available tests for the presence of reflux. Rigorous case definition is a prerequisite for any study, and particularly for studies on the effect of anti-reflux therapy on otolaryngological disorders. The introduction of intraluminal impedance testing may provide us with a tool to diagnose reflux with a degree of certainty that has been lacking until now.

ASPIRATION

Definition

Aspiration is the passage of foreign material beyond the vocal cords. This chapter will not cover acute airway obstruction due to aspiration of a foreign body, but rather the (usually chronic) aspiration of saliva, feeds and/or refluxed gastric contents.

Causes

The air and food passages cross to a much greater extent in man than in other mammals as a result of adaptations for speech, making us particularly predisposed to aspirate. A host of mechanisms exist to compensate for this and a deficiency in any one can lead to aspiration. Such deficiencies include impaired or incoordinate swallowing, impaired laryngeal sensation, impaired laryngeal elevation on swallowing and impaired true vocal fold adduction. Most commonly, aspiration presents in children with some combination of oesophageal dysmotility, poorly coordinated oral and pharyngeal phases of swallowing and impaired laryngeal reflexes resulting from neuromuscular disorders or cerebral palsy. Occasionally, oesophageal dysmotility can be an isolated phenomenon

in otherwise healthy infants.⁶⁵ Swallowing dysfunction may also be due to inadequate maturation of neurological control in premature infants. Many children who aspirate have reflux, but only a small minority of children with reflux will aspirate.⁶⁶ Laryngeal elevation is impaired by the presence of a tracheostomy tube and by endotracheal intubation, both of which predispose to aspiration, although aspiration can be reduced by applying positive pressure (positive-end expiratory pressure (PEEP) or continuous positive airway pressure (CPAP)).^{67, 68} Nasogastric tubes do not seem to be a risk factor.⁶⁹

Symptoms and signs

The typical clinical features in infants are apnoeas, bradycardias and choking attacks with feeds. There may be apparent life-threatening events (see above) and aspiration is not uncommon as a cause of sudden infant death.⁷⁰ Chronic aspiration may present as recurrent pneumonia. Aspiration may also occur without overt signs (silent aspiration), manifesting as progressive deterioration in respiratory function.

Diagnostic tests

The best available investigations at present are video-fluoroscopy and fiberoptic endoscopic evaluation of swallow (FEES).

The videofluoroscopic modified barium swallow (often referred to simply as videofluoroscopy) is usually carried out in conjunction with a speech and language therapist. Various consistencies of radio-opaque material, ranging from thin liquid to solid, are swallowed and followed on x-ray fluoroscopy. The investigation provides excellent information about the coordination and completeness of the oral and pharyngeal stages of the swallow, as well as the presence of aspiration. Videofluoroscopy is a detailed and dynamic investigation that provides considerably more information than a standard contrast swallow, whose only use in this regard is to exclude tracheo-oesophageal fistula and oesophageal stricture. [*]

FEES has the advantage over videofluoroscopy of being performed at the bedside or in the outpatient clinic. It may also be more sensitive for aspiration.⁷¹ The swallow is observed using a fiberoptic endoscope positioned just behind the soft palate via the nose. Coloured liquid is easiest to see. The investigation gives information about palatal elevation, leakage into the pharynx during the oral phase, pharyngeal residue and aspiration. Fiberoptic endoscopic evaluation of swallowing with sensory testing (FEESST) is an extension of the technique that also provides information on laryngeal sensation, although its use in children is less widespread. With experience and a cooperative child, FEES is possible even in very young children.⁷² [*]

It is possible to identify aspiration using oral administration of a radioactive substance which can be identified in the lungs on scintigraphy.^{73, 74} The procedure is extremely operator-dependent and the quality of the images obtained is poor. [*]

Endoscopy is useful in a number of ways. Micro-laryngoscopy-bronchoscopy under general anaesthetic is the only way to reliably exclude a laryngeal cleft, although a fiberoptic laryngoscopy should identify vocal cord palsy. Bronchoscopy (fiberoptic or rigid) allows bronchoalveolar lavage samples to be obtained for the identification of lipid-laden ('foamy') macrophages, although the sensitivity and specificity of this for aspiration has been reported to be poor.^{75, 76, 77} [***]

Management

Minor degrees of aspiration may be managed by altering the consistency of feeds according to the results of the videofluoroscopy. A speech and language therapist should supervise this, and will also be able to give advice on head positioning during feeds. The decision to stop oral feeds in infants in favour of tube feeding should not be taken lightly as it may be extremely difficult for oral feeds to be re-established in a child who has not developed the necessary oral skills early in life. Tube feeding (either by nasogastric tube or gastrostomy), however, is often unavoidable. [*]

Where aspiration of refluxed gastric contents is a major problem, control of the reflux by fundoplication may be helpful. Equally, if aspiration of saliva is a major issue despite tube feeding, a procedure to reduce saliva production may be beneficial. This may take the form of excision of the submandibular glands with bilateral parotid duct ligation,⁷⁸ or alternatively simple ligation of all four major salivary gland ducts.⁷⁹ Injection medialization of a paralyzed vocal cord may reduce aspiration⁸⁰ but carries a risk of impairing the airway. [**]

Tracheostomy will often make aspiration worse by preventing laryngeal elevation on swallowing. It does, however, allow easy access to the chest for suctioning and may, of course, be indicated for other reasons in these children with multiple problems. Even a cuffed tube does not prevent aspiration as secretions pool above the cuff and the seal is never perfect. Tubes are available with a low-pressure cuff and a suction port above it if this is a problem. [*]

Ultimately, when all else has been tried, it may be necessary to consider a procedure to separate the air and food passages completely. Laryngotracheal separation is the procedure of choice and has the advantage over both laryngeal closure (suturing the false cords together above a tracheostomy⁸¹) and total laryngectomy, being reversible, at least in theory. The procedure involves transecting the cervical trachea and bringing out the lower end as

a permanent end-stoma. The upper end of the trachea can be closed off as a blind pouch or anastomosed end-to-side to the oesophagus. The procedure produces good results and may allow the resumption of oral feeds.^{82, 83} However, this is at the expense of voice. Most children considered for this procedure will be nonverbal but the decision to sacrifice speech is clearly one that cannot be taken lightly. [**]

KEY POINTS

- The following are risk factors for aspiration:
 - cerebral palsy;
 - neuromuscular disorders;
 - impaired oesophageal motility;
 - prematurity;
 - gastro-oesophageal reflux;
 - tracheostomy.
- The following otolaryngologic diagnoses should be considered:
 - laryngeal cleft;
 - tracheo-oesophageal fistula;
 - vocal cord palsy.

Best clinical practice

- ✓ A speech and language therapist should be involved from the outset. [Grade C/D]
- ✓ Videofluoroscopy and/or FEES are the investigations of choice. [Grade C/D]
- ✓ Endoscopy has a role in certain situations. [Grade C/D]
- ✓ Alterations in feed consistency may be all that is required in mild cases. [Grade C/D]
- ✓ Tube feeding is often necessary. [Grade C/D]
- ✓ Fundoplication and salivary surgery have a small but important role. [Grade C/D]
- ✓ Laryngotracheal separation surgery is effective but sacrifices voice. [Grade C/D]

Deficiencies in current knowledge and areas for future research

Few centres treat large numbers of children, so most of the published literature consists of relatively small retrospective case series. Any large, prospective evaluation of diagnostic tests or treatment options would be a useful addition to current knowledge.

SEARCH STRATEGY

The author's extensive bibliography on congenital and acquired diseases of the oesophagus in children was supplemented with a Medline search using the key words oesophagus, child, congenital, caustic, achalasia, oesophageal stenosis, tracheo-oesophageal fistula and tracheomalacia. The Cochrane library was also consulted. Mr Colin Bailie FRCS, Consultant Paediatric Surgeon at the Royal Liverpool Children's Hospital advised the section editor before completion of the final draft.

EMBRYOLOGY

The oesophagus and trachea first become identifiable as separate structures when the embryo is 22–23 days old. The lung bud appears as a median ventral diverticulum in the developing foregut. Shortly thereafter, the primitive stomach appears as a fusiform enlargement immediately caudal to the diverticulum. The oesophagus develops from the short area between the tracheal diverticulum and the stomach. As the trachea and oesophagus elongate, ridges appear in the lateral walls. Fusion in the midline of these ridges separates the trachea from the oesophagus. The separation process commences caudally, proceeds cranially and is complete between days 34 and 36 of gestation. Elongation of the oesophagus relative to the rest of the developing foetus begins in the distal portion and is complete by seven weeks. Kluth cast doubt on the lateral ridge theory of oesophagotracheal separation and proposed an alternative dorsal and lateral ridge theory.¹

The circular musculature of the oesophagus appears in the sixth week and by the end of that week innervation by the vagus nerve has commenced. During the seventh and eighth weeks, the epithelium of the oesophagus proliferates to such an extent that the lumen is virtually, but not completely, occluded. Initially, the epithelium is ciliated but it is gradually replaced by stratified squamous epithelium (see Chapter 65, Head and neck embryology).

OESOPHAGEAL ATRESIA

In oesophageal atresia, part of the wall of the oesophagus fails to develop. In most cases this is associated with a failure of complete separation of the developing trachea – hence the persistence of a tracheo-oesophageal fistula. This was a uniformly fatal congenital abnormality until 1939 when Levin and Ladd independently reported the

first two survivors. Both infants required multiple procedures – cervical oesophagostomy, feeding gastrostomy and subsequently oesophageal substitution. The first successful primary repair of the defect, which paved the way for future developments, was achieved by Haight, in 1941.^{2,3} It is now rare for an infant with oesophageal atresia to succumb from oesophageal atresia alone, unless it is associated with extreme prematurity or a major congenital cardiac defect.^{4,5}

Incidence

Abnormalities in oesophageal development are present in 1:3000–4000 live births. There is no standard genetic pattern of inheritance, although the condition has been documented in siblings, in one and very occasionally in both twins and in two generations.⁶

Pathogenesis

The anomaly is thought to arise between the third and sixth weeks of intrauterine development. The precise cause and mechanism are unknown. Failure of complete separation of the foregut from the respiratory tract would appear to be the basis for the development of the various types of defects.^{7,8,9} Oesophageal atresia may occur as an isolated anomaly but at least 50 percent of cases have additional malformations.

Types of anomaly

The variety and incidence of the different types of tracheo-oesophageal abnormalities are shown in **Table 101.1**. It is especially important for the otolaryngologist to be alert to the possibility of a tracheo-oesophageal fistula without oesophageal atresia ('H' type) as this may present in later childhood with recurrent respiratory infections. It may be discovered as an incidental finding at bronchoscopy, when a suction canula in the tracheal lumen is found to enter the fistula. Often the tracheal orifice can be concealed in a mucosal fold. It may

Table 101.1 Different types of tracheo-oesophageal anomalies.

Type of anomaly	%
Oesophageal atresia with distal tracheo-oesophageal fistula	87
Oesophageal atresia without tracheo-oesophageal fistula	6–7
Oesophageal atresia with proximal tracheo-oesophageal fistula	2
Oesophageal atresia with proximal and distal tracheo-oesophageal fistula	1
Tracheo-oesophageal fistula without oesophageal atresia	3–4

sometimes be recognized at flexible bronchoscopy in a newborn baby.¹⁰

Associated anomalies

Additional congenital malformations are found in approximately one-half of infants with tracheo-oesophageal anomalies. The various systems affected are as shown in **Table 101.2** with multiple defects occurring in many patients.¹¹ The mortality in oesophageal atresia is directly related to the severity of associated congenital anomalies particularly cardiac defects, and the degree of prematurity (**Table 101.3**).^{4,5}

The VACTERL complex

The VATER complex of associated anomalies was described by Quan and Smith in 1973.¹² (The acronym stands for V = vertebral, A = anorectal, T-E = tracheo-oesophageal fistula and (o)esophageal atresia, R = radial and renal dysplasia.) This was subsequently extended to the VACTERL association to include cardiac and limb abnormalities.

Ventricular septal defects are the single most common cardiac malformation.¹³ Of the gastrointestinal anomalies, duodenal atresia, Meckel's diverticulum and malrotation are most commonly encountered. A variety of genitourinary anomalies may be present in association

Table 101.2 Congenital anomalies associated with oesophageal atresia/tracheo-oesophageal fistula.

Type of anomaly	%
Cardiovascular defects	34
Vertebrae anomalies	17
Gastrointestinal (excluding anorectal) anomalies	14
Genitourinary anomalies	12
Anorectal malformations	11
Skeletal defects	11
Respiratory anomalies	6
Genetic/chromosomal defects	2
Miscellaneous anomalies	10

Table 101.3 Risk classification for infants with oesophageal atresia.

Group	Birth weight (g)	Major cardiac anomaly	% Survival
I	> 1500	No	> 95
II	< 1500	Or Present	60
III	< 1500	PLUS Present	25

with oesophageal atresia, the most serious being bilateral renal agenesis (Potter's syndrome), which is fatal. The anorectal anomalies are equally divided between the supralelevator (high) and translevator (low) defects.

Diagnosis

Polyhydramnios is nonspecific but is present in approximately 90 percent of mothers of infants with oesophageal atresia. Antenatal ultrasound scan may be indicative of oesophageal atresia without fistula when there is failure to demonstrate the presence of intragastric fluid.¹⁴ To confirm the diagnosis of oesophageal atresia suspected on prenatal ultrasound scan, Langer, and later Levine, have proposed magnetic resonance imaging.^{15, 16, 17} The overall prognosis for these foetuses is poor, due to the high incidence of chromosomal abnormalities.¹⁸ Of 16 cases of prenatally diagnosed oesophageal atresia, only 4 (25 percent) survived the neonatal period. The infant, at birth, is 'excessively mucousy' and requires repeated suction as it is unable to swallow saliva. Failure to recognize the anomaly at this stage will expose the infant to choking episodes and aspiration pneumonitis with the first feed. The diagnosis is confirmed by passing a large calibre (No. 10 French) firm catheter through the mouth and into the oesophagus. The position of arrest of the tube is confirmed on a chest x-ray (**Figure 101.1**). If the tube enters the stomach, there is no oesophageal atresia. In the majority of cases with this condition the tube cannot be advanced more than 10 cm beyond the lower gum margin. It is important to include the abdomen on the original x-ray in order to assess the presence of intestinal gas shadows (**Figure 101.2**). Gas within the gastrointestinal tract implies the presence of a distal tracheo-oesophageal fistula while the distribution of the gas may indicate an additional intestinal anomaly, e.g. duodenal atresia. The chest radiograph should be assessed for pulmonary pathology and the configuration of the heart shadow may be indicative of cardiac defects, e.g. Fallot's tetralogy.

Management

Treatment of infants with oesophageal atresia should be concentrated in centres where the surgical expertise, supportive services (anaesthesia, paediatric intensive care, radiology, pathology) and specialized nursing care are available. Transfer to such centres should be prompt to avoid exposing the infant to the risks of aspiration pneumonitis. The infant is transported in a portable incubator either in a lateral position or in the prone position in order to discourage reflux of gastric juice into the distal tracheo-oesophageal fistula, while continuous suction is applied to the upper pouch to prevent

Figure 101.1 Plain x-ray of the chest and upper abdomen in an infant with oesophageal atresia. The radiopaque tube can be seen in the upper oesophagus. Gas in the intestines indicates the presence of a distal tracheo-oesophageal fistula.

aspiration of saliva. Definitive repair may have to be postponed in the presence of aspiration pneumonitis, which generally responds very rapidly to broad-spectrum antibiotics and physiotherapy. [***] In the infant with severe respiratory distress requiring mechanical ventilatory support, consideration should be given to emergency ligation of the distal tracheo-oesophageal fistula to facilitate respiratory support and to prevent overdistension of the stomach and intestine.¹⁹

SURGICAL REPAIR

The operative procedure is carried out under general endotracheal anaesthesia. Preliminary bronchoscopy to document the level of entry of the tracheo-oesophageal fistula, to assess tracheomalacia and to exclude an upper pouch fistula is recommended. Access is achieved via a right posterolateral extrapleural thoracotomy through the fourth or fifth intercostal space. After dividing the azygos vein, the distal oesophagus is identified and traced proximally to its site of entry into the trachea. The fistula is divided and the tracheal defect closed with fine

Figure 101.2 Plain x-ray of the chest and abdomen in an infant with oesophageal atresia. The tip of the catheter can be seen at the thoracic inlet. The gas pattern in the abdomen indicates the presence of a duodenal atresia ('double bubble').

interrupted nonabsorbable sutures. The proximal blind end of the oesophagus is identified in the apex of the chest and mobilized sufficiently to effect an anastomosis with as little tension as possible. An end-to-end anastomosis is performed using a single layer of sutures (**Figure 101.3**).

The operative correction of oesophageal atresia has recently been carried out thoracoscopically, but this requires considerable expertise and can only be safely carried out in specific centres.^{20, 21} [**/*]

An oesophagomyotomy,²² oesophagoplasty²³ or the use of elective paralysis and mechanical ventilation for a few days postoperatively in an extremely tight anastomosis may be effective in reducing the incidence of anastomotic complications.

The passage of a fine transanastomotic nasogastric tube through the nose into the stomach will allow enteral feeding to commence on the second or third postoperative day. A gastrostomy tube is no longer indicated in the routine repair of an oesophageal atresia. In fact,

the fashioning of a gastrostomy exposes the infant to an increased incidence of gastro-oesophageal reflux which predisposes the anastomosis to stricture formation.²⁴ [**/*]

Oral feeding has been introduced as early as the second postoperative day but is generally postponed until three to four days after surgery.

A contrast oesophagogram may be performed on the fifth postoperative day to check the anastomosis.

Patients with a long gap between the proximal and distal segment (particularly those with an isolated oesophageal atresia) require special attention. The alternative approaches available are to delay the repair pending differential growth of the oesophageal segments towards each other (three months), or to perform a cervical oesophagostomy and carry out an oesophageal substitution at a later stage – colonic interposition,²⁵ gastric tube²⁶ or gastric transposition.²⁷

Results and prognosis

The survival rate for infants born with oesophageal atresia has improved significantly due to improved operative technique, better anaesthesia and greatly improved postoperative intensive care. The main determinants of survival are birth weight above 1500 g and the presence or absence of a significant cardiac anomaly.

Complications

Complications of oesophageal atresia repair may be divided into early and late.

- **Early complications** include anastomotic leak, strictures, recurrent tracheo-oesophageal fistula and vocal cord palsy.
- **Late complications** comprise tracheomalacia, gastro-oesophageal reflux and disordered oesophageal peristalsis.

ANASTOMOTIC LEAKS

The incidence varies from 4 to 36 percent, depending on the vigour with which the diagnosis is pursued. [***] The majority of leaks are insignificant and are mainly detected on routine contrast studies. Minor leaks seal spontaneously but may lead to stricture formation. Major leaks present within 48–72 hours postoperatively and cause respiratory distress due to tension pneumothorax. They may be amenable to direct repair if promptly diagnosed, or to conservative treatment by intercostal drainage. Cervical oesophagostomy and gastrostomy may be the safest approach if there is a major disruption of the anastomosis.

Figure 101.3 The technique of repair of oesophageal atresia with distal tracheo-oesophageal fistula. (a) Division of distal tracheo-oesophageal fistula; (b) closure of tracheal defect with interrupted sutures; (c) end-to-end oesophago-oesophageal anastomosis with a single layer of interrupted sutures.

ANASTOMOTIC STRICTURE

The stricture produces symptoms such as dysphagia or recurrent respiratory infections due to aspiration. The incidence varies from 10 to 50 percent. Strictures are

caused by poor anastomotic technique, ischaemia, anastomotic leakage or gastro-oesophageal reflux. Most strictures respond to one or two dilatations but intractable strictures generally fail to respond to dilatations

alone until the associated gastro-oesophageal reflux is corrected.¹¹ [***]

RECURRENT FISTULA

Recurrent fistulae develop in approximately 8 percent of patients.²⁸ The diagnosis should be suspected in a child who develops respiratory symptoms during feeding or who suffers repeated respiratory infections. The investigation of choice is a tube oesophagogram with confirmation at bronchoscopy. Surgical division of the fistula is the only reliable method of treatment.

TRACHEOMALACIA

This is due to a weakness of the tracheal cartilaginous ring structure and is characterized by partial or complete occlusion of the tracheal lumen, primarily during expiration.²⁹ It occurs in 10–20 percent of patients and is responsible for 'near miss' apnoeic and/or cyanotic attacks or recurrent respiratory infections. The condition affects the distal trachea and is diagnosed on bronchoscopic examination, which reveals the slit-like aperture of the trachea during expiration. Treatment is controversial. Many authors claim that the problem resolves spontaneously in time but the infant is at risk of sudden death. Aortopexy, in which the ascending segment and arch of the aorta are elevated and attached to the posterior surface of the sternum, should be considered.³⁰ Tracheomalacia is covered in Chapter 88, Congenital disorders of the larynx, trachea and bronchi.

VOCAL CORD PALSY

Vocal cord palsy may take place in association with a tracheo-oesophageal fistula or one or both recurrent laryngeal nerves may be traumatized during tracheo-oesophageal fistula surgery. The nerves are at most risk during the cervical repair of an H-type tracheo-oesophageal fistula. Vocal cord palsy is considered in Chapter 88, Congenital disorders of the larynx, trachea and bronchi.

GASTRO-OESOPHAGEAL REFLUX

Careful investigation will reveal gastro-oesophageal reflux in up to 60 percent of children undergoing successful repair of oesophageal atresia. Various factors have been implicated in the pathogenesis of the reflux, particularly disordered oesophageal motility, displacement of the gastro-oesophageal junction and the use of a gastrostomy. The reflux causes recurrent vomiting which may lead to aspiration and respiratory infections or may produce a stricture at the anastomotic site. The diagnosis is established on barium oesophagogram and on pH monitoring. Medical treatment is successful in many cases but antireflux surgery may be necessary in selected

cases.^{31,32} Gastro-oesophageal reflux is covered in detail in Chapter 100, Gastro-oesophageal reflux and aspiration.

DISORDERED PERISTALSIS

Swallowing difficulties may persist for many years as a result of the inherent oesophageal dysmotility, affecting the distal segment in particular.³³ The infant gradually learns to cope with this problem unless there is an associated anatomical defect (anastomotic stricture, gastro-oesophageal reflux or distal oesophageal stenosis).

RESPIRATORY INFECTION

These infants are also prone to recurrent respiratory infections during the first few years of life. Children who have had a tracheo-oesophageal fistula repair often develop a troublesome recurrent cough ('tracheo-oesophageal fistula (TOF) cough'), due to a combination of factors including a tendency to aspiration, mild tracheomalacia and gastro-oesophageal reflux. Many require ongoing care from a multidisciplinary team including an otolaryngologist.

CONGENITAL OESOPHAGEAL STENOSIS

Congenital stenosis of the oesophagus is rare. Stenosis most commonly arises from acquired lesions, e.g. reflux oesophagitis, corrosive ingestion, foreign body impaction or secondary to surgical resection and anastomosis. The congenital form may be caused either by a membranous web or diaphragm, or may arise as a result of intramural deposits of tracheobronchial cartilaginous tissue. The latter pathology has been most frequently reported in association with oesophageal atresia and/or tracheo-oesophageal fistula.³⁴

Clinical features

In the presence of a complete web, presentation is similar to that of oesophageal atresia, with symptoms appearing on the first day of life. In other cases, symptoms may develop at any stage of life through to adulthood but generally arise in early infancy. The symptoms include dysphagia, vomiting with food ingestion, failure to thrive, recurrent respiratory infections and foreign body impaction.

Diagnosis

Gastro-oesophageal reflux as a cause for the stenosis should always be excluded. The barium oesophagogram will identify the site of the lesion. Congenital webs are most commonly located in the middle third of the oesophagus and appear as shelf-like projections within

the oesophageal lumen. Tracheobronchial remnants are generally located in the lower third of the oesophagus or at the gastro-oesophageal junction and they cause sharp narrowing at this point. The precise nature and anatomical location of the lesion should be confirmed by endoscopic examination.

Treatment

Dilatation alone may be sufficient for many oesophageal webs. [*/*] Surgical resection of tracheobronchial cartilaginous tissue is generally recommended.³⁵ [*/*]

ACHALASIA

Achalasia is a motility disorder of the oesophagus characterized by an absence of peristalsis and failure of relaxation of the lower oesophageal sphincter.³⁶ This causes obstruction at the level of the oesophago-gastric junction.

Incidence

Achalasia is rare in children. The incidence is one per 100,000 and approximately 5 percent of all patients with achalasia are symptomatic before the age of 15 years. There are few reports of achalasia being present in siblings^{37, 38} and it has been reported in association with a number of syndromes, e.g. Riley-Day syndrome. Evidence for a familial incidence of the disease is lacking. Both sexes are equally affected.

Aetiology and pathogenesis

The aetiology of achalasia is unknown. Oesophageal dysmotility is also found in Chaga's disease, scleroderma, oesophageal atresia, diabetes and secondary to gastro-oesophageal reflux, but the unique feature of achalasia is the constantly nonrelaxing lower oesophageal sphincter.

There are numerous theories regarding pathogenesis, the primary defect being described variously as neurogenic, myogenic and hormonal. There is evidence that it is the result of an abnormality of parasympathetic innervation. Absence of ganglion cells in the myenteric plexus in the dilated portion of the oesophagus with normal ganglion cells in the distal nondilated segment has been described.³⁹ This, however, is not a constant feature and is reflected in the variable reports of the histopathology of some of the specimens of oesophageal muscle. These range from the total absence of ganglia, to the presence of normally ganglionated muscle or abnormal ganglion cell morphology. [****] Histochemical staining for acetylcholinesterase may reveal the presence of ganglion cells and nerve trunks in the myenteric plexus,

although their numbers are slightly reduced. Reports using electron microscopy and intestinal polypeptide hormonal assay support the theory that this is a neurogenic disorder.⁴⁰

Diagnosis

SYMPTOMATOLOGY

The principal symptoms of achalasia in childhood consist of vomiting, dysphagia, chest pain and weight loss. Dysphagia with the sensation of food sticking in the lower oesophagus and postprandial vomiting are the most frequent presenting symptoms. Retrosternal or epigastric pain manifests in one-third of the patients and in a few cases it is the primary presenting symptom. Weight loss of varying extent occurs in one-half of the patients. Nocturnal regurgitation may give rise to respiratory symptoms resulting in recurrent respiratory infections. Diagnostic delay is the norm with an average duration of symptoms prior to diagnosis of 24 months. Many children are treated for long periods for 'cyclic vomiting' or for 'anorexia nervosa'.

RADIOLOGICAL FEATURES

If achalasia is suspected, order a chest x-ray and a barium swallow in consultation with a colleague in the radiology department. The plain chest radiograph may show a dilated food-filled oesophagus with an air-fluid level in the distal third. In addition, there may be radiological signs of repeated aspiration pneumonitis. The chief characteristics on barium oesophagogram are a dilated oesophagus, the absence of a stripping wave, incoordinated oesophageal contractions and obstruction at the oesophagogastric junction with prolonged retention of barium in the oesophagus. Failure of relaxation of the lower oesophageal sphincter leads to the classical rat-tail deformity of funnelling and narrowing of the distal oesophagus (**Figure 101.4**).⁴¹

ENDOSCOPY

Oesophagoscopy contributes little to the diagnosis, but retained food may be found within the dilated oesophagus. The main value of endoscopy is to exclude organic causes of obstruction in the oesophagus.

OESOPHAGEAL MANOMETRY

The diagnosis of achalasia is best confirmed by oesophageal motility studies using a constantly perfused catheter technique. The criteria for the diagnosis are:

- a high-pressure (>30 mmHg) lower oesophageal sphincter zone;

Figure 101.4 Barium swallow in a child with achalasia of the oesophagus with the classical 'rat-tail' deformity of the distal end.

- failure of the lower oesophageal sphincter to relax in response to swallowing;
- absence of propulsive peristalsis;
- incoordinated tertiary contractions in the body of the oesophagus (Figures 101.5 and 101.6).

Treatment

Three treatment options are available for the management of achalasia: pharmacological manipulation, forceful

dilatation and oesophageal myotomy with or without the addition of an antireflux procedure.

PHARMACOLOGICAL TREATMENT

The manipulation of oesophageal motility disorders using pharmacological and dietary measures has been disappointing. [*] Reports of the use of isosorbide dinitrate and nifedipine have been more encouraging.⁴² [*/*] Nifedipine is a calcium entry blocker and since calcium ions are directly responsible for the activity of myofibrils and consequently the tension generated, their use in reducing the pressure in the lower oesophageal sphincter in achalasia, or for the vigorous oesophageal spasms, seems logical. Prostaglandin E₂ has also been employed with some success. Its value in the long-term treatment of achalasia remains to be proven. The injection of botulinum toxin has not been a success in children.^{43, 44} [*/*]

FORCEFUL DILATATION

Good palliation may be obtained by dilatation. The most commonly used dilator consists of a single bag of fixed diameter which is inflated with water (Plummer) or air (Browne-McHardy, Rider-Moeller).

Dilatation has been advocated as the treatment of choice in adults. Fellows *et al.*⁴¹ showed that, following pneumatic dilatation in adults, only 10 percent of patients subsequently required cardiomyotomy. In children, success rates ranging from 40 to 60 percent have been reported.^{45, 46} [***] The aim of forceful dilatation is to disrupt the muscle fibres of the lower oesophageal sphincter. There is, however, no evidence that the muscle fibres tear rather than stretch. Vantrappen and Janssens⁴⁴ were unable to distinguish histologically between sphincter segments in dogs and monkeys subjected to forceful dilatations and those from normal controls. In general,

Figure 101.5 Oesophageal motility study in a normal child showing progression of the peristaltic waves through the oesophagus. DS, dry swallow.

Figure 101.6 Oesophageal motility study in a child with achalasia showing completely incoordinate oesophageal contractions. WS, wet swallow.

older patients respond better to pneumatic dilatation.⁴⁷ A report of 899 adult patients treated at the Mayo Clinic concluded that myotomy was more successful and safer than dilatation, poor results being obtained twice as frequently following dilatation as after myotomy.⁴⁵ The incidence of perforation following pneumatic dilatation varies from 1 to 5 percent.

SURGICAL PROCEDURE

Cardiomyotomy, as originally described by Heller in 1914, is the basis of all surgical procedures. The technique involves splitting the muscle fibres along the whole length of the lower oesophageal sphincter. The controversies concern the length of the oesophageal myotomy, the distance which the myotomy extends onto the stomach and the necessity for including an additional antireflux procedure.⁴⁸

CORROSIVE INJURY TO THE OESOPHAGUS

Accidental ingestion of caustic substances by children has become relatively uncommon in the developed world. This is as a result of government legislation regulating the use of caustics in commercially available drain cleaners and the introduction of child-proof containers. Parental awareness of the dangers has also contributed. In the developing world, lye burns to the oesophagus are still an enormous public health problem and a significant cause of mortality and of much long-term morbidity.⁴⁹

Pathophysiology

Caustic soda (sodium hydroxide) ingestion can cause severe injury to the oropharynx, oesophagus or stomach. The strong alkali rapidly penetrates the body tissues

producing an intense acute inflammatory reaction and oedema. If the concentration of the solution is high, transmural penetration occurs with resulting destruction of the musculature of the oesophagus, penetration into the peri-oesophageal tissues with mediastinitis or frank oesophageal perforation. The acute phase is followed by sloughing of the necrotic tissue and replacement by granulation tissue. The final outcome varies from complete resolution in the mild case to extensive fibrosis of the entire oesophagus. The extent and severity of the injury are directly related to the concentration of the lye ingested (liquid lye is more damaging than the granular form), the quantity ingested and the duration of contact.^{50, 51}

Clinical presentation

There is extensive oedema and swelling of the mouth and lips and the child is unable to swallow. There may be chest pain if large quantities of lye reach the stomach. Haematemesis, dyspnoea, stridor and other respiratory symptoms develop as a consequence of the resulting oedema or from direct laryngeal injury. Fibrosis of the lips and temporomandibular joint may develop as a result of severe oropharyngeal burns (**Figure 101.7**).

Diagnosis

It is important to ascertain whether the lye was actually ingested or whether it entered the oral cavity only. Early endoscopic examination, within 12–24 hours of the injury, should be undertaken to determine whether or not the oesophagus is affected. Assessment of the extent of oesophageal burn is not possible at this early stage and endoscopic examination is terminated, once evidence of oesophageal injury is encountered, to minimize the risk of perforation.

© Hodder Arnold / Scott-Brown 7E

Figure 101.7 Fibrosis of the lips following severe oropharyngeal burns secondary to caustic soda ingestion.

An early contrast oesophagogram will reveal the extent of the injury, determine the presence of a perforation and act as a baseline for evaluating future stricture formation (**Figure 101.8**).

Treatment

EMERGENCY

Admission to hospital of all suspected cases is imperative.

Vomiting should not be induced. No neutralizing agents should be given as these produce heat when interacting with the corrosive substance and increase the severity of the injury.

CONTINUED MANAGEMENT

Initial treatment should consist of broad-spectrum antibiotics and intravenous fluids. [**] The use of steroids (prednisolone 2 mg/kg/day)⁵² as advocated by Haller and Bachman,⁵³ has been questioned and, in a prospective controlled trial, Anderson found steroids to be of no benefit.^{53, 54} [**/*] Ulman⁵⁵ similarly found no objective evidence to support the use of steroids; nevertheless many clinicians feel a three-week course of prednisolone is helpful and it is widely used. If, on endoscopy, no oesophageal injury is found, active treatment is stopped and the patient is discharged. If a burn is found, antibiotics are continued for ten days. Oral feeds are commenced as soon as the child is able to tolerate fluids. A gastrostomy for feeding purposes may be necessary in cases with severe burns. In these patients, the opportunity may be taken to pass a string through the oesophagus to act as a guide for future dilatations. Another option is to stent the oesophagus early after ingestion of the caustic substance.^{56, 57} [**/*]

A repeat oesophagogram is carried out three weeks after ingestion of the lye and oesophageal dilatations are commenced if a stricture is found. The dilatations

Figure 101.8 Barium oesophagogram in a child following ingestion of caustic soda. There is extensive stricture formation of the distal half of the oesophagus.

are repeated at regular intervals until the stricture is eliminated. Ninety percent of oesophageal strictures will respond to dilatation. The remainder will require oesophageal replacement.⁵⁸

KEY POINTS

- Polyhydramnios is nonspecific but is present in approximately ninety percent of mothers of infants with oesophageal atresia.
- Fifty percent of babies with oesophageal atresia have additional malformations.
- It is now rare for an infant to succumb from oesophageal atresia alone, unless it is associated with a major heart defect or extreme prematurity.

- Ten to twenty percent of children with tracheo-oesophageal fistula have tracheomalacia which is responsible for 'near miss' apnoeic and/or cyanotic attacks or recurrent respiratory infections.
- In the developing world, lye burns to the oesophagus are still a serious public health problem, a significant cause of mortality and the source of much long-term morbidity.

Best clinical practice

- ✓ Treatment of infants with oesophageal atresia should be concentrated in centres where the surgical expertise, supportive services (anaesthesia, paediatric intensive care, cardiology, radiology, pathology) and specialized nursing care are available. Transfer to such centres should be prompt. [Grade B]
- ✓ The diagnosis of oesophageal atresia is confirmed by passing a catheter through the mouth and into the oesophagus. If the tube enters the stomach there is no oesophageal atresia. [Grade C/D]
- ✓ If achalasia is suspected, order a chest x-ray and a barium swallow in consultation with a colleague in the radiology department. [Grade C/D]

Deficiencies in current knowledge and areas for future research

- Knowledge of the embryology of the gastrointestinal tract and the genetic basis for congenital anomalies is growing.
- Better support services including paediatric intensive care facilities for infants with major congenital anomalies of the aerodigestive tract continue to improve survival.
- Multidisciplinary clinical input – including otolaryngologists – is likely to be increasingly accepted as routine for continuing care of these children.
- Greater awareness of the dangers of lye burns and legislation to improve containers for caustic agents would greatly reduce the misery of these injuries, particularly in the developing world.

SEARCH STRATEGY

This chapter is supported by a PubMed search using the key words children, ENT, imaging, radiology, ultrasound, magnetic resonance, computed tomography, bronchography, play therapy, scintigraphy and sialography.

INTRODUCTION

Paediatric ear, nose and throat (ENT) imaging is a challenging subject both for the radiologist and the otolaryngologist. In addition to the anatomical complexities of middle and inner ear structure, the convolutions of the turbinates, the pneumatization pattern of the sinuses, and the dynamics of the swallowing mechanism, both the radiologist and the surgeon need to be aware of the variations during normal growth of the child.

Many of the imaging techniques used in paediatric ENT radiology are similar to those used in adult practice (**Table 102.1**), but the diseases encountered may be entirely different. Consideration of the need for sedation or general anaesthesia is an important factor when deciding to image a child.

The number of plain radiographs performed in children has significantly diminished over recent years with the widespread availability of computed tomography (CT), especially for imaging the ear and sinuses. It is

Table 102.1 Imaging modalities pertinent to paediatric ENT radiology.

Imaging modalities	
Plain radiography	Mastoid views, lateral soft tissue neck, limited role for sinus views
Fluoroscopy	Videofluoroscopy, contrast swallows, bronchography, sialography, chest and diaphragm screening
Ultrasound	Including Doppler and colour flow studies
Computed tomography	Standard, helical, high resolution, contrast-enhanced and angiography
Magnetic resonance imaging	Including angiographic sequences, perfusion and possibly functional studies
Nuclear medicine	Thyroid, parathyroid and salivary scintigraphy, perchlorate discharge test
Interventional procedures and angiography	Percutaneous biopsy and aspiration, balloon dilatation, stent placement, embolization

important to minimize radiation exposure in children and in this context magnetic resonance imaging (MRI), which avoids the use of ionizing radiation, has an expanding and important role. Dynamic contrast bronchography is also being used in some centres for 'real-time' assessment of the upper airway, particularly in ventilated children when it can be combined with simultaneous pressure measurements to give valuable information about opening airway pressures.

IMAGING MODALITIES

Plain radiographs (x-rays)

Much of the older radiological literature details an array of radiographic projections and plain x-ray tomographic techniques to assess the airway, petrous bone and mastoid region. These have now largely been replaced by cross-sectional imaging (CT and MRI). There is still a limited role for mastoid views to define the extent of pneumatization of the air cells, but this should be restricted to requests from ENT specialists. The projections obtained are no different to those used in adult practice. Plain radiography of the airway is usually limited to a lateral film and in this instance air acts as a negative contrast medium outlining the anatomical details. For the most reliable results, the film should be obtained during inspiration with the neck slightly extended. This is because there is considerable variation in the appearances of the soft tissues of the nasopharynx in the young child dependent on posture. This is especially so when the neck is flexed and the child is breathing out, when apparent soft tissue swelling can mimic a pharyngeal mass. A high kilo-voltage radiographic technique with added tube filtration ('Cincinnati view') also used to be recommended for airway assessment, but this is no longer necessary following the development of digitally enhanced computed radiography, CT and MRI, all of which give much better detail. Sinus x-rays are difficult to interpret in the young child, where mucosal thickening can be a normal finding. They should be avoided in the under five year olds,¹ [***] and should be restricted to requests by ENT specialists only. In the acute setting, they are indicated to exclude fractures and foreign bodies. Radiology for nasal bone fractures should be deferred until 10–14 days have elapsed since injury, and even then are rarely clinically indicated. Despite all the advances in imaging technology, it is important to remember that a chest x-ray can still be very informative, particularly to detect air-trapping and foreign body inhalation.

Fluoroscopy

Fluoroscopy is the study of sequential dynamic images. Techniques pertinent to paediatric ENT radiology include

videofluoroscopy of the swallowing mechanism, videofluoroscopy during phonation, barium or contrast swallows, tracheo-oesophageal fistul-o-grams (TOF-o-grams), chest and diaphragm screening, sialography and dynamic contrast enhanced bronchography.

Radiographic assessment of the swallowing mechanism and phonation studies require fluoroscopy of the upper airway and palate. The assistance of a speech and language therapist is mandatory for best results. For the assessment of swallowing, sequential analysis of the swallowing cycle requires recording of data on videotape or other media storage device for later analysis. In general, screening in the lateral position will suffice. Most children require assessment with various types of food consistency. Yoghurt mixed with barium, thickened barium and liquid barium should generally be assessed, with other foodstuffs used as appropriate. The examination should be modified depending on the child's age and feeding habits.

For phonation studies, ideally a small quantity of barium is administered to each nostril and then sniffed to coat the soft palate. Clearly barium may have to be omitted in the very young child. Fluoroscopy is performed with the child in a modified Towne's (chintuck) position to obtain a tangential view of the velopharyngeal portal and then subsequently in the lateral projection. When no barium has been administered, only the lateral projection is performed.

Barium and water-soluble contrast studies are useful for assessing the oesophagus for strictures, vascular rings, gastro-oesophageal reflux and oesophagitis. Barium is the preferred contrast agent, unless aspiration is highly likely, or in the postoperative state where a suitable water-soluble agent is preferred. The procedure is similar to that performed in adults, although it will need alteration with young children who are usually fed supine rather than erect. A modified technique is required to demonstrate a tracheo-oesophageal fistula (TOF), the technique often referred to as the 'TOF-o-gram'. In this procedure the child has a nasogastric tube placed into the stomach and lies in a prone position. The tube is incrementally withdrawn while injecting a suitable contrast agent and simultaneously screening the oesophagus in a lateral projection. The effect of gravity and the careful withdrawal of the tube under direct vision is felt to enhance the chances of identifying a fistula. [*]

Diaphragm screening is a simple procedure involving visualization of diaphragmatic movement during normal respiration, coughing, sniffing and Valsalva manoeuvres. The degree of diaphragmatic excursion and presence or absence of paradoxical movement should be recorded. Fluoroscopy can also be used to assess air-trapping if inhaled foreign bodies are suspected.

Some children require dynamic 'real-time' evaluation of the airway using bronchography. A small quantity of nonionic water-soluble contrast is injected into the trachea and bronchi and the airway is then screened to assess changes in airway calibre during the respiratory

cycle. This is limited to children requiring ventilatory support and should only be carried out with full resuscitation facilities available. Clearly its use is restricted to specialized paediatric centres. It is mainly used for confirmation of suspected anatomical abnormalities where there is doubt or to confirm the extent of tracheobronchomalacia and evaluate airway opening pressures.^{2,3} [**]

Sialography of the parotid or submandibular glands can be performed in children. The technique is similar to that performed in adults, although the procedure may need to be carried out under anaesthesia in the younger child. Sialectasis, stone formation and ductal abnormalities may be identified. Sialography may be combined with CT or MRI examinations. Sialography has also been performed successfully using a digital subtraction technique to obtain superior image quality.⁴ [**] MR sialography, using heavily T2-weighted sequences, is a noninvasive alternative to cannulation techniques, but is unable to provide the excellent spatial resolution (and therefore image quality) that can be obtained with a formal sialogram.⁵ [**]

Ultrasound

Ultrasound (sonography) is a noninvasive, portable and easily accessible method of assessing the neck and thoracic inlet. Importantly, it uses no ionizing radiation. Ultrasound should be the first imaging investigation for a neck mass, although it has a limited role in assessing deeply placed pathologies (Figure 102.1). It is especially good at distinguishing solid from cystic lesions (e.g. thyroglossal cysts). Combined with Doppler and colour flow imaging, ultrasound provides vital information about the vascularity of masses, such as haemangiomas and cystic

Figure 102.1 Ultrasound is a readily available, noninvasive technique which can quickly distinguish solid from cystic lesions – this scan shows a lymph node.

hygromas. Ultrasound has also been used successfully to assess the unossified, cartilaginous structures of the larynx.⁶ [**] It has the advantages of providing real-time images under physiological conditions and may be useful in assessing vocal cord movement,⁷ but it has not yet replaced direct inspection of the cords at endoscopy. [***]

Ultrasound can also evaluate diaphragm movement, although in practical terms this is often restricted to the intensive care unit setting when the child cannot be moved easily for fluoroscopic assessment. It can also guide biopsy and aspiration of neck lesions, although this is carried out much less frequently in children than adults.

Computed tomography

Plain x-ray tomography is now a technique of the past. CT provides good soft tissue characterization, but excels in the definition of fine bony detail. With the development of faster scan times, helical scanning and improved resolution, CT can now provide superb images of the middle and inner ears (Figure 102.2), although it is less effective at assessing the retrocochlear auditory pathway.⁸ [**] The major drawback for CT, however, is its use of ionizing radiation. Generally, high resolution 1 mm scans should be obtained in two planes, the transverse and the coronal, although with some of the more modern scanners transverse images can be obtained and then the coronal images reconstructed from the scan dataset, without loss of detail and negating the need to do two scans. This helps to reduce the radiation exposure to the child. The images should all be post-processed using a sharp filter to improve bony detail. CT of the petrous temporal bone complements MRI and is essential in preoperative assessment for cochlear implants.

CT also has a role in the assessment of children's sinuses and the nasal airway, although this is much less frequently required than that in adults. It is particularly pertinent in children with orbital cellulitis, where contrast-enhanced CT will define the presence and extent of retro-orbital disease much more clearly than clinical examination. [**] Evaluation of choanal atresia is also facilitated by defining the bony elements on CT, although this often requires mucosal decongestants and suction of nasal secretions to improve the sensitivity of the scan.

Volume acquired CT information using helical or electron beam scanners can be used to assess the upper airway, including the larynx,⁹ [**] and may be used to generate 'virtual' bronchoscopic images (Figure 102.3). This is a significant step forward in imaging terms, but it still falls short of the fine detail which can be seen with direct vision.

CT angiography is rapidly approaching the degree of definition previously provided only by formal invasive angiography, and this can be extremely helpful in conditions such as juvenile nasopharyngeal angiofibroma.

Figure 102.2 Transverse CT image through the petrous bone showing: (a) a dilated vestibule; and (b) a Mondini abnormality of the cochlea.

Magnetic resonance imaging

MRI is a noninvasive, multiplanar imaging technique with excellent soft tissue discrimination. Importantly for children, it does not use ionizing radiation, but unfortunately may require sedation or anaesthesia. It is a rapidly advancing technology in which numerous acronyms are used to describe the multitude of imaging sequences used. In simple terms however, T1-weighted sequences provide anatomical definition and T2-weighted sequences demonstrate areas of high fluid content, in particular oedema. MRI excels in the demonstration of the brain and spinal cord. However, there is increasing use of MRI, not just to assess the posterior fossa and other intracranial structures, but also inner ear abnormalities. T2-weighted sequences

Figure 102.3 Single transverse image from CT virtual bronchogram dataset clearly shows the carina.

provide the optimum information about the inner ear, clarifying the presence of fluid filled structures, such as the cochlea, vestibule and semicircular canals, but occasionally T1-weighted and post-contrast images may be helpful. Vestibular schwannoma is an uncommon condition in children and most imaging in the cerebello-pontine angle is focussed on identifying other mass lesions, the brainstem and the seventh and eighth nerves. When intracranial extension of disease processes in the ear or paranasal sinuses occurs, there may be involvement of the venous sinuses. Magnetic resonance (MR) venography provides a noninvasive method of assessing involvement of these venous sinuses (**Figure 102.4**).¹⁰ Further advances in MR technology now also permit exquisitely detailed three-dimensional reconstructions of the inner ear.¹¹ [**]

Velopalatine movement can also be successfully assessed with MRI, using fast T1-weighted sequences during phonation of different sounds and replaying them in cine mode.^{12, 13} [*] In cooperative children this may be a satisfactory alternative to videofluoroscopy, although this does require MR scanners of high specification.¹⁴

The excellent soft tissue discrimination of MRI can also be effectively used in imaging the neck when, after ultrasound, MRI is the next most useful imaging modality (**Figure 102.5**). It is especially helpful in defining the extent and nature of cystic masses, such as cystic hygromas (**Figure 102.6**), when extension into the thoracic inlet can also be assessed. Parotid and sub-mandibular gland assessment is also more accurate with MRI. Fat-suppressed MRI (e.g. STIR or 'short tau inversion recovery' sequences) are especially useful in identifying lymphadenopathy and adenoidal and tonsillar tissue.

MR angiography is now a viable alternative to invasive formal angiography, especially for the assessment of vascular malformations. However, formal angiography may still be required for endovascular treatment of lesions.

Nuclear medicine

Nuclear medicine has an important role in assessment of the thyroid and parathyroid glands. It can be used to

Figure 102.4 Coronal MR venogram, a noninvasive study, showing absent flow in the right transverse venous sinus consistent with venous thrombosis.

Figure 102.6 MR images include (a) coronal T1-weighted and (b) transverse T2-weighted scans of the neck showing an extensive cystic hygroma extending into the nasopharynx and posteriorly around the neck.

Figure 102.5 Coronal T1-weighted MR images of the neck show a discrete lesion in the right parotid gland later proven to be a pleomorphic adenoma: (a) pre-contrast; (b) post-contrast.

assess the presence, size and distribution of thyroid and parathyroid tissue, and is most frequently used in young children with hypothyroidism. The usual technique for evaluating the thyroid gland involves the injection of ^{99m}Tc pertechnetate and is similar to that performed in adults. Alternatively ^{123}I iodine can be used. In some children there may be abnormalities of organification of iodine into tyrosine and this can be assessed with the perchlorate discharge test (**Figure 102.7**).¹⁵ [**] Parathyroid assessment is now more easily performed using ^{99m}Tc -labelled sestamibi to identify increased parathyroid metabolism.¹⁶ [**] Salivary scintigraphy can also be performed in children to assess parenchymal function and excretion of the salivary glands.¹⁷ [*] Its main indication is in the assessment of connective tissue disease and occasionally to look for salivary duct obstruction when sialography cannot be performed.

Interventional procedures and angiography

Most interventional techniques in children require the assistance of sedation or, more commonly, general anaesthesia to ensure a safe, controlled procedure. Percutaneous biopsy of head and neck lesions is much less commonly performed in children, but the technique is similar to that performed in adults. Aspiration of cysts under ultrasound or CT control is effective and when appropriate can be combined with sclerotherapy, for example for treatment of extensive cystic hygroma.

The primary treatment for tracheobronchial stenosis remains surgery, but there are now radiological interventional alternatives, such as balloon dilatation and

Figure 102.7 Time-activity curve from a perchlorate discharge test demonstrates displacement of activity from the thyroid confirming an organification defect.

insertion of metallic stents. Balloon dilatation is performed under fluoroscopic guidance, and can be repeated if necessary. Stent placement again requires fluoroscopic guidance, but the long-term effects of these placements have yet to be fully evaluated.¹⁸ [*]

Formal angiography is an invasive technique requiring placement of an intravascular catheter usually by the femoral artery, and subsequent contrast injection to delineate the vessels (**Figure 102.8**). Obtaining vascular access in young children can be a challenge and selective vessel catheterization may also be difficult, although children do not usually suffer from atherosclerotic vessels encountered in adult practice! Diagnostic studies should be combined with interventional procedures if possible. Embolization for vascular head and neck lesions can be used for definitive treatment or preoperatively and involves selective catheterization and usually particulate embolization or injection of sclerosant.¹⁹ [**]

RADIATION PROTECTION

Of paramount importance when considering whether a child needs a diagnostic test is balancing the need and quality of the information the test will provide with the risk associated with the test. A useful test is one in which the result, whether positive or negative, will affect patient management or improve confidence in the clinician's diagnosis. The prime area of concern in radiological

Figure 102.8 Formal angiography demonstrates abnormal vascularity within a lobular mass in the right side of the neck.

imaging is the risk from ionizing radiation. Radiological tests are an accepted part of medical practice in which clinical benefits should clearly exceed the small radiation risk. Statutory regulations in the UK, The Ionizing Radiation (Medical Exposure) Regulations 2000, require all involved to reduce unnecessary exposure of patients to radiation.²⁰ This is especially important in children, in whom there is increased sensitivity to the effects of radiation. One important way of reducing the radiation burden to a patient is ensuring unnecessary tests are avoided, especially avoiding repeat examinations.

It is useful to consider radiation dose in terms of the total radiation risk to the body, calculated from the sum of the doses to a number of body tissues. The weighting factor for each tissue varies upon its relative sensitivity to radiation-induced cancer or severe hereditary effects. This gives a single effective dose to the body. It is also useful to consider the effective dose in terms of chest x-ray equivalents. **Table 102.2** gives typical effective doses for a number of examinations pertinent to paediatric ENT radiology.²¹ It is important to note that a CT examination administers a relatively high radiation dose and thus it is certainly worthwhile considering alternative imaging modalities such as ultrasound and MRI.

PATIENT PREPARATION

General approach

It is important that children and their parents understand why any imaging test has been requested and what to expect from the examination. This information is best addressed initially in the outpatient environment during the consultation process, but is usually supplemented by information provided by the radiology department. Information, both verbal and written, needs to be appropriate for both child and adult. Some examinations require venous access and this can be distressing for both the child and their carer. The use of topical anaesthetics and play therapists using distraction techniques can be

hugely beneficial, and make the procedure both pain free and uneventful. Indeed, the importance of access to play therapy for children has recently been recognized at governmental level in the UK National Service Framework (NSF) document.²² When intravenous contrast agents will be required, it is important to notify the radiology department of any allergies or previous problems with contrast agents to ensure the procedure can run smoothly. The choice of contrast agent, the examination technique or even the particular modality to be used to image the child may be modified depending on the history provided.

Where complex procedures (such as angiography) require sedation or general anaesthesia, the child will need admission to a ward and appropriate preparation, depending on the particular procedure to be performed. Informed consent is mandatory for invasive procedures.

Sedation and general anaesthesia

For some imaging tests, particularly those requiring long periods of immobility such as MRI, young children will require sedation or general anaesthesia. Plain x-rays and ultrasound rarely require either, whereas interventional studies and angiography for head and neck lesions almost invariably require general anaesthesia. Particular care must be exercised in using sedation in children with airway problems, especially in the MR environment where the child may spend some time within the bore of the magnet. It is also mandatory to have appropriate MR compatible monitoring equipment in such circumstances (**Figure 102.9**).

The choice of sedation or anaesthesia will depend on local practice and expertise. In general, children under the age of four to five years will require some form of assistance to maintain adequate immobility to ensure diagnostic images. Very young children, under three months, can often simply be fed and wrapped up well. Children older than five years or weighing more than 20 kg are often difficult to sedate adequately, and it may

Table 102.2 Typical effective doses from diagnostic medical exposure.

Diagnostic procedure	Typical effective dose (mSv) ^a	Equivalent number of chest x-rays	Approximate equivalent period of natural background radiation
Chest (single PA film)	0.02	1	3 days
Skull	0.06	3	9 days
Barium swallow	1.5	75	8 months
CT head	2.0	100	10 months
Thyroid (Tc-99 m) radionuclide scan	1	50	6 months
Ultrasound	0	0	0
Magnetic resonance imaging	0	0	0

^aUK average background = 2.2 mSv per year, range 1.5–7.5 mSv.

© Hodder Arnold / Scott-Brown 7E

be prudent to proceed directly to general anaesthesia. Some of the faster CT scanners are reducing the tendency to require sedation or anaesthesia, and play therapists can be especially useful in the MR environment for fidgety children.²³ [*//*] There are many different regimens for sedation and **Tables 102.3** and **102.4** show only two examples. Sedation protocols will need to be developed depending on local equipment and expertise and with close cooperation between the departments of radiology, ENT and anaesthesia. It is important to reiterate that the MR environment requires specialized, MRI-compatible monitoring equipment, which must at all times be readily available.

Table 102.3 Possible sedation regimens, part 1.

Age	Fasting time (hours)		
	Clear fluids	Milk	Solids
<Three months	2	4	6
>Three months	2	6	6

Table 102.4 Possible sedation regimens, part 2.

Weight	Suggested drug, 1 month to 18 years
<20 kg	Oral chloral hydrate 100 mg/kg body weight, maximum dose 2000 mg May be supplemented with rectal paraldehyde, unless neutropenic 0.3 mL/kg body weight + 0.3 mL/kg of olive oil, maximum dose 10 mL paraldehyde + 10 mL olive oil
>20 kg	Consider oral quinalbarbitone 7.5–10 mg/kg body weight, maximum dose 200 mg

KEY POINTS

- Plain sinus radiography is of limited use in children.
- Ultrasound is the first line imaging investigation for a neck mass.
- Bony detail is best demonstrated by CT.
- When cross-sectional imaging is considered necessary, ultrasound and magnetic resonance imaging should be considered as alternatives to CT to minimize the radiation burden to the child.
- Magnetic resonance imaging provides excellent soft tissue imaging in multiple planes and can be used to provide noninvasive angiographic information.
- Sedation or anaesthesia may be needed for examinations which are time-consuming and require prolonged immobility of the child.

Best clinical practice

The following is a brief summary of imaging pathways for investigating some common paediatric ENT problems. The reader is referred to the relevant areas elsewhere in the book for more detail.

Craniofacial malformations

- ✓ CT with multiplanar reconstruction – for bone and soft tissue demonstration.
- ✓ MRI – for midline defects with a possible intracranial extension.

Deafness and prior to cochlear implantation

- ✓ CT to assess the temporal and parietal bones and middle ear, cochlear morphology and cochlear patency.²⁴
- ✓ MRI to assess cochlear morphology, cochlear patency and the retrocochlear auditory pathway.²⁵

Trauma to the head and face

- ✓ CT for complex fractures.

Paranasal sinus disease

Plain sinus radiographs should be limited to requests from ENT specialists. Indications include:

- ✓ single occipitomeatal (OM) or lateral view for foreign body;
- ✓ single OM view to confirm maxillary opacification prior to antral washout in suspected maxillary empyema;
- ✓ otherwise low-dose CT.

Neck masses including lymphadenopathy

- ✓ Ultrasound, with or without colour Doppler imaging – often the only imaging examination required to confirm lymphadenopathy.
- ✓ CT or MRI.

Airway obstruction

- ✓ Lateral soft tissue view of the neck.
- ✓ Chest x-ray.
- ✓ Barium swallow.
- ✓ Contrast enhanced CT or MRI – if a vascular ring is suspected.

- The development of imaging agents which act at a cellular or molecular level may provide therapeutic as well as diagnostic advances.
- The role of functional MR in evaluating the auditory pathway needs further investigation.²⁶

Deficiencies in current knowledge and areas for future research

- Many of the imaging techniques used in paediatric ENT radiology have not been evaluated in an evidence-based manner, but have crept into routine use as custom and practice allowed. As some techniques, such as helical CT, impart a considerable radiation burden on the child and are becoming more readily available, it is important that any advances are carefully assessed to ensure their impact on clinical care is beneficial.
- Although advances in imaging technology have provided the opportunity to display pathology as a three-dimensional entity, it remains unclear what quantifiable benefits this provides the surgeon.
- The long-term effect of interventional procedures requiring insertion of implants, such as tracheal or bronchial stents, is unknown.

SEARCH STRATEGY

Much of the material for this chapter is based on anecdotal cases. This is supported by a manual search of *Clinical risk* (www.rsmmpress.co.uk/cr.htm) and a search of the site <http://www.lawreports.co.uk>. Standard textbooks of medical law were also consulted.

INTRODUCTION

The reader is referred to Chapter 48, Medical jurisprudence and otorhinolaryngology, for an outline of the principles of medical jurisprudence. This chapter and the foregoing are based on the law in England and Wales and the definition of 'negligence' as applied by courts in this jurisdiction. In summary, 'negligence' requires that the aggrieved party establish that there was a duty of care, that there was a breach of that duty and that harm followed. The standard of care is that of the reasonably skilled and experienced doctor. The appropriate test, known as the *Bolam* (*Bolam v Friern Hospital Management Committee*)¹ test, states that it is:

the standard of the ordinary skilled man exercising and professing to have that special skill. A man need not possess the highest expert skill; it is well-established law that it is sufficient if he exercises the ordinary skill of an ordinary competent man exercising that particular art.

Despite differences in the legal framework within which otolaryngologists work, depending on their geographic area of practice, it is hoped that the principles discussed here are applicable internationally. The focus is on optimum care for children.

Approximately two-fifths of the workload of a typical National Health Service department of otolaryngology is in the management and treatment of ENT disorders in children. The vast majority of children attending an ENT department have common conditions that are not especially challenging to diagnose; the operations involved are usually straightforward to perform, with low surgical risk. Tumours in general, and head and neck cancers in particular, are rare in children. Recognition of rarities, such as cavernous sinus thrombosis or tuberculosis of the middle ear in an infant, may be delayed and give rise to litigation, but patterns of error with more common pathologies occur and the aim of this chapter is to convey practical advice as to how best to avoid these patterns rather than dwell on the esoteric.

HEARING DISORDERS

Delayed diagnosis

Although parents may be convinced that there has been a significant delay in the diagnosis of a child with profound hearing loss, it is often difficult for them to prove this. Often the child will have passed the health visitor screening tests early in life; the claimant may find it difficult to establish that these were improperly undertaken and led to the wrong conclusion. A child may be born with a mild to moderate hearing impairment, which gradually deteriorates.

A delay in diagnosis of meningitis may also account for a claim for profound hearing impairment. In the case of pneumococcal or meningococcal meningitis this may amount to only a matter of hours, and there is often dispute as to whether the signs and symptoms of meningitis were evident at the time when the first doctor missed the diagnosis at the onset of the illness. If not, a case can be defended successfully as there is evidence that the onset of profound deafness is early in the course of the disease, especially in pneumococcal cases. In one case, tuberculous meningitis was misdiagnosed as a viral infection, despite the fact that at the same time the child's mother had just been diagnosed with open tuberculosis. Nobody had linked the presence of the tubercular cough as being a likely source of infection and cause of the baby's ill health.

Establishing damages

Even if there is clear evidence from general practitioner (GP) records that a child's mother attended on frequent occasions complaining about the child's ability to hear, the mother may have grave difficulties in establishing that the child has been damaged by any delay that may have occurred. The problem becomes more difficult if the child has other developmental abnormalities, particularly if they affect language development. A child in whom the diagnosis is delayed until the age of, say, two and a half years may then be fitted with hearing aids and it is uncertain what deleterious effect the delay brought about. If the child is older and the optimum time for fitting a cochlear implant has been missed, then the prospect of the child developing the ability to understand spoken language and to communicate orally may have been lost. With a trend toward earlier implantation (Chapter 70, Paediatric cochlear implantation) it may become more difficult to argue that diagnostic delay did not bring about adverse consequences. This is a complex issue and there are those in the deaf community who would hold that not having the opportunity of a cochlear implant is no loss at all.

Negligent causation

Profound deafness at birth may arise from a negligent act in the antenatal period. For example, in one case a mother was established as lacking immunity to rubella following the birth of her first child. The hospital failed to arrange a rubella vaccination, as did the GP. A year later the mother attended at nine weeks gestation with her second pregnancy, having just contracted rubella. The general practitioner reassured her that, as it was coming to the end of her first trimester, there was no risk to the foetus of damage from the maternal rubella infection. As a result of this advice, the mother decided not to pursue a termination of the pregnancy, which had been her original intention. The child was born profoundly deaf, and after many years of protracted litigation, the case settled in 1994 in favour of the claimant, for a total of £300,000, including £50,000 general damages.

Deafness wrongly diagnosed

Litigation may also arise due to decisions made on the false assumption that the child has a profound hearing impairment. In the young infant and toddler, a detected hearing loss assessed by brain stem evoked response audiometry, may give thresholds in the region of 80 dB. The child may be fitted with hearing aids, and educational decisions based on a hearing difficulty may lead the child to be placed in a school for children with special needs. Such a child may also have a fluctuating conductive hearing loss, due to otitis media with effusion, and the true sensorineural thresholds may only become established when the child reaches five or six. At this point, it may become clear that the hearing impairment is only in the order of 30 to 40 dB, and that placement in a mainstream school can be considered. Such parents often feel very aggrieved.

They may feel that their child is being disadvantaged educationally and attempt to seek compensation. Although the diagnosis in such circumstances of the degree of hearing loss may have been incorrect, it is usually impossible for the claimant to establish that alternative management would firstly have been instituted, and secondly would have led to a materially different and improved outcome.

CHOLESTEATOMA

Diagnostic or treatment delay

Delay in diagnosis usually occurs due to a failure of the GP to refer a child with a chronic aural discharge. Occasionally, particularly in those cases of congenital cholesteatoma with an intact eardrum, a mother may

have attended either the GP, and/or the hospital, complaining that their child has a unilateral hearing impairment. It is quite permissible in those children under the age of eight, particularly if the tympanogram is abnormal, to wait the usual three months for a middle ear effusion to resolve. If the condition has not resolved, then serious consideration should be given to an examination of the ear under anaesthesia, and if there is any doubt, a CT scan. Plain radiography often gives a clue in these cases, due to the loss of the septae in the air cell system, as well as the cloudiness due to the presence of the cholesteatoma.

Although parents may be aggrieved by the delay in diagnosis, they are usually unable to establish that any additional damage has occurred as a result of the delay, unless there has been an intracranial complication.

If children have been referred and diagnosed and placed on the waiting list for excision of a cholesteatoma, complications such as facial nerve paralysis, meningitis or other intracranial sepsis may occur whilst the child is on the waiting list. In these cases it is rarely possible to prove negligence, as it is difficult for the claimant to establish that the waiting list has been managed such as to amount to providing substandard care. However, whether increased delays by some patients cause by prioritizing 'long waiting' patients amounts to negligence has not been tried in the courts. Cholesteatomas are often large in children despite a relatively short history and consequently it is probably only a matter of time until there is a challenge to waiting list management arguing that a child with a cholesteatoma should be given priority over an adult who may have waited longer. This may be especially so today as waiting list management is increasingly being taken out of the hands of consultants who know the patients and is being controlled more by hospital managers. As such managers are not medically qualified, there is an argument that the Bolam principle should not apply.

Negligent management

Sadly, surgical management of paediatric cholesteatoma is poor in many areas. In matters of consent, the consequences of open cavity surgery on future employment prospects are often not discussed. If a parent discovers that the open-cavity operation which his son received barred him from working offshore, when he was not told of the long-term effects of such surgery, he may seek redress through the courts. As there is a potential for a claim for life-long loss of earnings, such an error on consent could be expensive.

Technical errors in performing mastoid surgery are still all too common. In one case, an aural polypectomy was performed which revealed cholesteatoma. Several months later, an atticotomy for cholesteatoma was undertaken on the same ear. Five days following surgery the child was admitted to another hospital with meningism and

cerebritis. An exploration of the ear was undertaken by an experienced ear surgeon who found that extensive cholesteatoma still remained. This was despite the operation note for the atticotomy indicating that all cholesteatoma was removed. The case was settled for an interim payment of £15,000 as fortunately, the child had made a full recovery from the brain infection, but should epilepsy subsequently develop then further compensation would be paid.

Facial nerve injury may complicate cholesteatoma surgery in children. Occasionally there is a defence. From time to time the nerve is in an abnormal position or more commonly is exposed by extensive disease. Provided the principle of identifying the nerve in an area of normal anatomy and an appropriate drill technique has been employed, a defence may be possible. Ideally, video or photographs of the operative findings make the matter much easier. A detailed operative note and a corroborating intraoperative note made by another surgeon are helpful. Nevertheless, most cases cannot be defended. The situation is often confounded by incorrect management of the palsy in the postoperative period due to a failure to explore the nerve or to provide good reasons with electroneuronographic evidence for not doing so.

CONGENITAL FIXATION OF THE STAPES

Rarely, a child may present with a conductive hearing loss and no middle ear effusion or significant past history of middle ear suppuration. This may be misdiagnosed in the older child as otosclerosis and surgery recommended. In these circumstances a range of congenital abnormalities can be present and not be recognized by the inexperienced. When a stapedotomy is attempted, the result is frequently a dead ear secondary to a perilymph 'gusher'. Problems may also arise from attempting to perforate a mobile thin footplate. This happens when the anterior crus is attached to the promontory rather than to the footplate. This abnormality, rather than a fixed footplate, accounts for the conductive loss. Correct management is to either divide the anterior crus alone or else close the ear. It is rare that poor outcomes from stapes surgery in children can be defended. Not only do surgical errors occur, but also often the consent has been inadequate, not taking into account the special problems of such surgery in children. Where a stapedectomy is planned in a child under ten, most experts in the field would expect that high definition CT scans of the cochlear and vestibular aqueducts had been obtained beforehand. Congenital abnormalities of the inner ear are a specific contra-indication to such surgery.

Matters become more complex in the case of the adult with congenital fixation of the stapes, as not surprisingly there are often no records from childhood. The past history of childhood hearing loss is then erroneously ascribed to otitis media with effusion.

ATLANTO-AXIAL INSTABILITY

Children with trisomy 21 (Down syndrome) have a high risk of atlanto-axial instability. This can result in excessive movement of the odontoid process during anaesthesia, such as to cause pressure on the spinal cord and neurological dysfunction, including permanent tetraplegia (**Figure 103.1**). It is often the anaesthetist that is blamed, especially if the induction has been fraught and the parent was present. However, it is more likely that it is the surgeon and the theatre team that cause this event by over-vigorous movement of the head while the child is hypotonic under the anaesthetic, often with muscle relaxants. High-risk children should be assumed to have the disorder. The practice of ordering routine plain radiographs of the cervical spine prior to surgery on Down syndrome children is outdated and no longer appropriate. It is more important to ensure that all theatre personnel move the child's head with extreme care. There is a salutary lesson to be learned with reference to this: a case was brought after a myringoplasty from which the child awoke with a partial tetraparesis. Postoperative radiology indicated that it was a rotational injury probably caused by the surgeon pushing the head away from himself to get a view of the anterior margin of the perforation whilst trying to position the graft. The mother dropped the case when she learned that it was more likely that the surgeon rather than the anaesthetist had caused the injury, as she liked the surgeon and thought he was a kind and caring doctor.

TONSILLECTOMY AND ADENOIDECTOMY

Dental damage

Most anaesthetists will advise that loose milk teeth are removed prior to surgery and consequently inhalation

Figure 103.1 Atlanto-axial subluxation.

of a milk tooth is unusual. Occasionally, secondary dentition can get chipped in the older child. Many hospitals now have speedy internal access to dental services to effect a repair, which often forestalls litigation.

Consent and bleeding

One of the commonest sources of complaint revolves around postoperative haemorrhage. Many parents when they are giving consent do not grasp that a haemorrhage can be large, require a blood transfusion and even become life-threatening. Most parents will acknowledge that they were warned that bleeding could occur, but most do not have in their mind a collapsed, shocked child with a young doctor desperately trying to get venous access – or even worse medical and nursing staff showing signs of panic as they realize they are losing control of the situation. Parents who have come through this scenario with their child almost all say that they would not have consented had they known of this risk. Actual haemorrhage rates are between 5 and 10 percent with severe bleeds happening in approximately 1–2 percent (see Chapter 96, Tonsillectomy). A landmark case in October 2004 in the House of Lords (*Chester v. Afshar*)² now means that it is no longer necessary for the claimant to establish that had they known of the risk they would not have had the surgery; it is just necessary to establish that they would have delayed surgery whilst they sought further advice. This effectively means that it is now essential that every parent be warned of the risk of major haemorrhage and blood transfusion.

Occasionally, the haemorrhage can go unrecognized by nursing staff. This can happen when nursing staff do not follow postoperative instructions on monitoring, or worse carefully chart a rising pulse in a restless child up to the point that the child has a massive haematemesis or even loses consciousness.

Errors in the resuscitation of the shocked child may be less common now with the introduction of paediatric life support and advanced paediatric life support training courses.

Poor surgical technique

Diathermy burns in the mouth and on the lips are still produced. Considerable care needs to be taken especially if using diathermy dissecting instruments or scissors as these can cause large burns, particularly on the tongue. It is generally impossible to mount a defence.

Perforation of the palate – deemed to be due to negligent surgery – has been reported with diathermy dissection.

ACUTE EPIGLOTTITIS

Since the introduction of haemophilus influenzae B (Hib) vaccination, epiglottitis is on the decrease. Only one child died from epiglottitis in England and Wales between 2000 and 2002, while there were six adult deaths. In the recent past it was failure to diagnose or suspect the condition that would lead to a patient being sent home only to return hours later with grave breathing problems or even to die at home. Not only may it be a failure to recognize clinical symptoms and signs, but also the classical radiographic appearance can go unrecognized thus leading to an indefensible claim (see Chapter 87, Acute laryngeal infections).

Acute airway obstruction is more commonly due to acute laryngotracheobronchitis (ALTB or croup), especially in infants. If an artificial airway is needed this is now best managed by intubation (see Chapter 87, Acute laryngeal infections). The anaesthetist may wish to have an ENT surgeon standing by to undertake a tracheostomy should intubation be impossible and the airway become compromised. Emergency tracheostomy in this situation is nowadays extremely rare (see Chapter 86, Stridor). If the airway is not quickly secured, brain damage ensues. Whether substandard care is deemed to have occurred will depend on each individual case.

TRACHEOSTOMY

Problems with the operation being undertaken as a planned procedure are unusual. Rarely, in very young children a pneumothorax can develop as can injury to the brachiocephalic vein. In the immediate postoperative period, should the tracheostomy tube become dislodged then there can be problems with maintaining the airway. This is why the tube may be sutured to the skin or stay sutures placed on either side of the tracheal incision to help find the opening should the tube being dislodged (see Chapter 93, Tracheostomy and home care).

Most litigation relating to tracheotomy surgery can be attributed to complications arising from poor nursing care. Many patients who have tracheotomies have been long-stay patients on intensive care. These patients frequently have chest infections with production of thick secretions. The secretions leading to acute airway obstruction can block the tracheostomy tube. Speedy identification of the problem by close monitoring of the patient usually results in aggressive suction of the airway with saline lavage or bronchoscopy with lavage if necessary. If this does not cause a rapid relief of the problem, the tracheostomy tube can be removed altogether. Unfortunately problems arise on general wards where the nursing staff may have many patients to look after and are unfamiliar with tracheostomy care. Ward nurses on ENT and neurosurgery wards are often experienced in nursing tracheotomies patients but this

cannot be said for the other wards. The timid nurse is often frightened to introduce a suction catheter deep into the lungs. In fact it is failing to pass the catheter right through the tube into the trachea that leads to the deep part of the tube obstructing. Also, these nurses may not have been trained to undertake bronchial lavage to loosen secretions and so bronchial plugging happens which reduces the patient's oxygenation.

When the patient's airway obstructs, speedy removal of the 'inner' tube and aggressive suction is required. If there is no inner tube then rapid removal of the whole tracheostomy tube and insertion of a clean tube is required. The tracheostomy tube is then connected to an Ambu-bag for inflation of the lungs. Despite the obvious fact that the tracheostomy was undertaken for obstruction to the airway above the stoma, there have been cases where the nursing staff attempted ventilation via the mouth with a facemask and ignored the tracheostomy. It was only when the cardiac arrest team arrived that the blocked tracheostomy was dealt with, but by then severe brain damage had been sustained.

FOREIGN BODIES

The ear

The safest way to deal with a foreign body in the ear of a small child is under a general anaesthetic. Attempts to remove a foreign body from the ear without a general anaesthetic by syringing or the use of a strong electro-magnet are often successful and carry a low risk of injury. However, instrumentation of the ear in a fractious child can lead to serious injury; such an action cannot usually be defended. Fortunately the injury is usually just limited to laceration of meatal skin, but perforation of the eardrum and even complete avulsion of the stapes has occurred.

The nose

Failure to diagnose a foreign body is a common cause of complaint and even litigation. The presence of a unilateral or even bilateral foul nasal discharge, which does not settle, should alert the otolaryngologist to the possibility of a foreign body in the nose in a child. In most cases the mother has attended on several occasions at the GP, the accident and emergency department and the ear, nose and throat department where a junior doctor has failed to realize the significance of the problem.

It is a common practice to wrap the small child in a blanket, then to remove the foreign body. However, if this method is employed, it is vital that all care is taken to avoid injury and the practice should not be used on those at risk of atlanto-axial subluxation. Injury occurring in

these circumstances is difficult to defend when it could be argued that a general anaesthetic carries less risk.

The oesophagus

Problems usually only arise with sharp foreign bodies (**Figure 103.2**). The main risk is of perforation but often this can be defended with a sharp foreign body. However, litigation is more likely to arise when there is a delay in recognizing the perforation or inappropriate management once recognized (see Chapter 92, Foreign bodies in the ear and the aerodigestive tract in children).

The airway

Occasionally an inert foreign body can be present for some time before it is recognized. Complaint usually only arises when a significant symptom such as stridor is ignored and then subsequently it is found to have been due to a foreign body. An unjustifiable delay in undertaking an examination where a foreign body has been inhaled may lead to problems. This is especially so when the foreign body is of a vegetable material such as a peanut. The delay can lead to swelling of the peanut with subsequent obstruction to that lung segment and bronchiectasis.

Button batteries

This modern foreign body can cause considerable damage if left in place for any length of time. If they are left in place in the nose or oesophagus they cause caustic burns with marked swelling and a risk of subsequent stenosis. Litigation may arise if a child is not treated as an emergency but is left until the next available routine list.

Figure 103.2 Sharp oesophageal foreign body.

NECK MASSES

Adenopathy

Surgery may be considered to establish a histological diagnosis in persistent cervical adenopathy. Trauma to the accessory nerve with resultant shoulder drop can arise as a result of dissection in the posterior triangle. Parents need to be explicitly warned of this risk prior to surgery. Ultrasound imaging may avoid the need for surgery in some neck masses.

Salivary gland tumours in children

This is a complex group of disorders (see Chapter 99, Branchial arch fistulae, thyroglossal duct anomalies and lymphangioma). Claims usually arise because of delay in diagnosis or facial paralysis.

EPISTAXIS

In children, the commonest site for repeated epistaxis is the nasal septum. Cautery with silver nitrate is still commonly practised. This rarely causes a problem, but excessive use on both sides of the nasal septum at the same time can lead to a septal perforation. This can also occur when hot wire cautery is used. In occasional circumstances, a severe vestibulitis following the cautery may be a significant contributory factor. Usually, such a complication cannot be defended.

Trichloroacetic acid is still used in some centres to cauterize the nasal septum. This needs to be handled very carefully as if too much is applied it can run on to the upper lip and cause a permanent scar (see Chapter 81, Epistaxis in children).

NASAL TRAUMA

Delayed treatment

Nasal fractures with bony deformity should be reduced within at most ten days following the injury to avoid callus formation and rigid bony union. Delayed treatment may lead to permanent osseocartilaginous deformity which can only be corrected by septorhinoplasty. This may lead to a successful claim for negligence. It is essential to have a referral mechanism between accident and emergency departments and otolaryngology departments so that early assessment can take place and arrangements can be made for manipulation of a nasal fracture under anaesthesia. The decision to manipulate a nasal fracture is clinical. Plain x-rays have little to offer.

© Hodder Arnold / Scott-Brown 7E

Figure 103.3 Septal haematoma.

Septal haematoma

Failure to recognize acute septal haematoma can lead to a permanent deformity if a septal abscess subsequently develops (Figure 103.3). In most instances of septal abscess, a doctor has not previously examined the child but occasionally a haematoma is missed or is diagnosed but not drained. The saddle nose deformity that results can be difficult to correct and as such the compensation can be relatively expensive to cover the pain and suffering of additional surgery and the cosmetic deformity.

KEY POINTS

- Medical negligence cases involving children are relatively unusual given the number of children undergoing otolaryngological management.
- Children are eligible to apply for 'legal aid' in their own right irrespective of the wealth of their parents.
- Some common pitfalls which give rise to litigation may be avoided by the application of simple ground rules.
- The information which must be conveyed to parents, carers and children prior to treatment to ensure that consent is properly informed is much greater than at any time in the past.

Best clinical practice

- ✓ Suspicion of hearing loss in children warrants prompt and thorough investigation.
- ✓ Early recognition and urgent treatment of meningitis reduces the risk of post-meningitic deafness.
- ✓ Cholesteatoma in children may be rapidly progressive. Always exclude the diagnosis in a discharging ear and intervene promptly if it is suspected.

- ✓ Iatrogenic facial palsy in tympanomastoid surgery is almost always avoidable with good anatomical knowledge and attention to surgical technique.
- ✓ Should iatrogenic facial palsy occur, immediate re-exploration must be considered.
- ✓ Ensure that parents and carers are aware that postoperative bleeding following adenotonsillectomy can be severe.
- ✓ It is prudent to warn that such bleeding may require blood transfusion
- ✓ Button batteries are potentially corrosive. When they present as foreign bodies they must be removed as soon as possible.
- ✓ Excision of neck nodes in the posterior triangle may be complicated by accessory nerve palsy; this should be explicitly discussed prior to surgery.
- ✓ Children with nasal trauma should be assessed by an otolaryngologist within days of the injury.

Deficiencies in current knowledge and areas for future research

The recent case of *Chester v. Afshar* will have a radical effect on consent in the future. It has moved practice toward the former American model of warning about everything, and virtually overturned the Bolam principle on consent. Furthermore, it applies even when the operation has been carried out in a competent manner.

In the future there will be an increased use of detailed leaflets for patients and, with the exception of emergencies, a 'cooling-off' period during which patients can reflect on the issues and consider whether they wish to go ahead with the prescribed treatment being considered best practice for all elective surgery. There may even be two consent forms to sign, the first when the patient agrees to surgery and the second after the 'cooling-off' period stating that they had considered the advice carefully.
